While the surgical treatment of gastric and duodenal ulcer is for the most part highly successful there remains a percentage of patients who are not cured or even relieved by surgical measures, and of that residuum probably the most unsatisfactory are the subjects of secondary ulceration, either gastro-jejunal or jejunal. I say they are the most unsatisfactory because not only are they not cured, but very often they are in a worse condition than they were before operation. This complication has occurred most frequently after the operation of gastro-enterostomy, and it has been stated that it does not follow operations of partial gastrectomy.¹ This, however, is not true, and cases are now beginning to be reported after these operations. The reason for this false impression is that until recently the operation of partial gastrectomy has largely been confined to cases of carcinoma, which practically never develop secondary ulcers, the necessary factor of hyperchlorhydria being absent. Now that partial gastrectomy has become established as a surgical treatment for gastric ulcer I have no doubt that an increasing number of cases will occur.

No variety of operative procedure on patients suffering from gastric or duodenal ulcer is immune from this complication, whether it be gastro-enterostomy, partial gastrectomy, excision of the ulcer, or pyloroplasty. From the published records, however, it would seem to be specially prone to follow operations for duodenal ulcer, operations en-Y, and with entero-anastomosis. The reason for this is the high degree of hyperchlorhydria which is usually found in duodenal ulcer, and, in the case of the special types of operation, the fact that the unneutralized gastric contents come into contact with jejunal mucosa.

It is believed by some that secondary ulcer is more likely to follow anterior than posterior gastro-enterostomy. It is very difficult to form a reliable opinion on this point, but what is evident from a study of the recorded cases is that true jejunal ulceration is relatively more frequent after anterior gastro-enterostomy, probably because the farther we descend the intestine the less tolerant it is to the action of the gastric juice.

The actual cause of the secondary ulceration is as obscure as the cause of the original ulcer for which the operative treatment was undertaken. That it is due in some way to the action of the gastric juice is evident from the situation of the ulceration—for example, on the anastomotic opening, on the jejunum opposite the stoma, on the efferent loop just beyond the anastomosis. That it is associated with hyperacidity is also beyond doubt, and probably this acidity is a factor in the production of the ulceration. We are still, however, in the dark as to the causation of the hyperacidity.

Errors in technique have been held to be largely responsible, especially the use of a Murphy's button or an unabsorbable continuous suture. In a series of cases I collected and published in the *British Journal of Surgery* (vol. vi) there were 14 cases out of 145 where Murphy's button had been used and 13 where an unabsorbable suture played an important part in the production of the ulceration. Nevertheless cases have occurred where catgut only has been employed.

The use of clamps and other technical methods have been blamed, but there is no definite proof that such methods are especially prone to be followed by ulceration. We are confronted with the fact that secondary ulceration may follow any technique and may even occur in the absence of hyperchlorhydria, though this is not common. We are driven to the conclusion, therefore, that the cause of the original ulceration is still at work in these cases, and has not been removed by the operation, and this is borne out by the great liability to recurrence in these patients, many of whom have been operated on repeatedly.

When we know the cause of gastric and duodenal ulceration we shall also know the cause of gastro-jejunal and jejunal ulceration.

* A paper read before the Liverpool and Manchester Medical Societies.

My object now is to analyse the small series of cases that have been under my care, with special reference to the surgical treatment that has been employed, and, if possible, to come to some conclusion as to the methods which are most likely to be successful. Most of these patients have been under observation for some considerable time—a condition which is essential if we are to form a true estimate as to the results of treatment. Many of the cases reported on as cured have been followed for only a few months after operation, a period which is much too short. My experience is that relapse is very common and may come on a year or more after operation.

I have had under my care seven cases of secondary ulcer, five of whom were originally operated on by me and two by other surgeons. Multiple operations have been done in most cases, and the results have been disappointing. I propose to give only a bare outline of the cases, and not to bore you with clinical details. The first three of these have been reported previously.

CASE I.

Male, aged 32. On May 6th, 1916, he had an anterior gastro-enterostomy for stenosis of the duodenum due to ulceration. Two rows of silk suture were used. In October, 1916, he had a sudden acute pain in the abdomen, and after this he had more or less continuous pain until December, 1916, when I reopened him. He had an ulcer of the efferent loop just beyond the anastomosis and adherent to the anterior abdominal wall. The ulcer was excised, and a silk suture, which was found lying in it, was removed. On October 3rd, 1917, he was living in Leeds, and had a sudden perforation, for which he was operated on in the Leeds Infirmary, the ulcer being sutured. Pain persisted after this operation, so that I operated on him again on November 29th, 1917. The ulcer was still present in the same place, and was still adherent to the anterior abdominal wall. The gastro-enterostomy was cut off, the opening in the stomach closed, and the affected loop of jejunum was resected and joined up by lateral anastomosis. A posterior no-loop gastro-enterostomy was then made, catgut alone being used. The patient remained well until the early part of 1919, when he began to have more indigestion. This persisted for some time, and did not really disappear until I fitted him with an abdominal support, as he had a fair degree of ptosis. Since then he states that he has felt a different man, and is now in good health.

CASE II.

Male, aged 40. He was operated on by another surgeon for duodenal ulcer in December, 1915, the operation being posterior gastro-enterostomy with two rows of linen thread. Pain recurred in a few months' time, and he was reopened by the same surgeon in September, 1916, who performed an entero-anastomosis. Much induration was noted at the site of the anastomosis, and a length of linen thread was removed when the entero-anastomosis was reopened. Pain rapidly recurred, and in December, 1917, I was asked to take him over, as his surgeon had to be absent on military service. On December 22nd, 1917, I operated on him, and cut off the anastomosis, which was the site of ulceration, and closed the openings in the stomach and the jejunum by a plastic operation. I excised the old duodenal ulcer, which was healed, by an elliptical incision, closing this transversely. The pylorus being patent, nothing further was required or done. Since that time the patient has been completely free from symptoms, and is now in perfect health.

CASE III.

Male, aged 43. Perforated duodenal ulcer in January, 1912. Suture of the perforation and posterior gastro-jejunostomy with silk sutures. Indigestion reappeared in two years' time. Second operation, April 25th, 1918. Much induration and contraction of the stomach and transverse mesocolon were found. The gastro-enterostomy opening was excised, the opening in the stomach was closed, and the cut ends of the jejunum were joined by end-to-end union. Radiographic examination later showed fair permeability of the pylorus, so nothing more was done. The patient remained in good health until about six months ago. Since then symptoms of stenosis have gradually developed, for which I propose to operate.

CASE IV.

Male, aged 49. Operation in August, 1918, for bleeding duodenal ulcer of three years' standing; posterior gastro-enterostomy and infolding of the ulcer; catgut alone was used for the sutures. Pain recurred six weeks after the operation. He was operated upon again on January 17th, 1920. An ulcer was found on the mesenteric border of the jejunum opposite the stoma. The anastomosis itself was free from ulceration. The anastomosis and jejunal loop were resected, the gastric opening was closed, and the jejunum joined by end-to-end union. A Koehler's gastro-duodenostomy was made because of the stenosis of the duodenum. After a period of freedom lasting several months the patient again reopened on December 3rd, 1921. The ulcer was again found to be at the site of the anastomosis. A gastro-enterostomy was again made, and the ulcer was closed. The patient remained well, but has some reflex vomiting owing to adhesions round the efferent loop—no doubt the result of repeated operative interference.

CASE V.

Male, aged 35. Operation, February 17th, 1917. Posterior gastro-enterostomy for duodenal ulcer. Relief for about six months, and then he had recurrence of pain and vomiting. A second operation

was done in June, 1920. Gastro-jejunal ulceration, with stenosis of stoma, was found, and the pylorus and duodenum were also stenosed. Pyloroplasty was done, resection of the stoma being left for a future sitting. This gave so much relief that nothing more has been done. For six months he was completely free from pain, but since then he has had occasional slight attacks of indigestion lasting about three days. His weight at the time of the second operation was 10 st.; now it is 12 st. 3 lb.

CASE VI.

Male, aged 40. Operation for perforated duodenal ulcer, October, 1919. Suture and posterior gastro-enterostomy (catgut only). Recurrence of pain three months later. Radiographically circular spasm of stomach was seen starting at stoma. Second operation, February, 1920. A small ulcer was found on the upper angle of the stoma. It was necessary to open the stomach to confirm this. The ulcer was excised locally, the resulting opening being closed with catgut sutures. The patient was readmitted to hospital on December 8th, 1920, suffering from severe haemorrhage. He was too ill for operation, and one pint of blood was transfused. He had a second, less severe haemorrhage on December 12th, and then began to improve. On January 21st, 1921, he was operated on, and a thickened and stenosed stoma was found; the site of active ulceration. An attempt at pyloroplasty failed to produce a satisfactory opening, and therefore a partial gastrectomy was done, the anastomosis being included in the portion removed. The technique employed was a posterior Polya en-Y as advocated by Moynihan.

The patient complained of pain again in September, 1921, and still has pain and, he says, vomiting. He has been admitted to hospital and dieted carefully, and never vomits while he is in, and also he gains in weight. Radiographic examination reveals nothing, the stump of the stomach emptying freely.

CASE VII.

Male, aged 47. Gastro-enterostomy in 1914 by another surgeon for pyloric stenosis. Relief for three years and then recurrence of pain. Latterly he has lost weight, but does not vomit unless he makes himself sick to relieve the pain. The radiographic report is as follows: "Stomach atonic and four inches low; moderately slow emptying through stoma." Second operation, December 6th, 1921. Active duodenal ulcer adherent to head of pancreas is still present. Stoma is much thickened and stenosed. The mesocolon is thickened and contracted. Partial gastrectomy by posterior Polya method was done.

When we analyse the methods employed in this small series we find that three have been left with the food taking the normal channel through the pylorus—namely, cases 2, 3, and 5. In two of these three cases no operation on the pylorus was necessary to enable the food to pass. In one a plastic operation was required. In two the gastro-enterostomy was cut off and in one it was left untouched—namely, case 5. The striking feature in this case was the rapid subsidence of symptoms when the plastic operation enabled the gastric contents to pass normally, and so relieved the stoma of the necessity of acting. The relief experienced was comparable to that afforded by the operation of gastro-enterostomy in duodenal ulcer with partial stenosis.

The results are: Cure in one case, where there was no pyloric stenosis originally, and where the original ulcer was excised at the time of the last operation. Relief for three years in a case where the pylorus was deformed, and then gradual onset of stenosis of the pylorus. Complete relief for six months and then partial recurrence of symptoms in the case where a plastic operation on the pylorus was necessary.

Two cases are left with a posterior no-loop gastro-enterostomy. In one (Case 1) there was a recurrence of symptoms about fifteen months after the last operation, but he is now well and eating ordinary food. I think the recurrent symptoms were possibly due to ulceration, though he has derived great benefit from wearing a ptosis support. The other patient (Case 4) is cured as regards ulceration, but has some reflux vomiting, which is controlled by gastric lavage.

Two patients have had partial gastrectomy (Nos. 6 and 7). No. 7 is too recent for any reliable opinion to be formed. No. 6 has pain, but how far one can rely on his statements is a little doubtful as he is a pensioner, and while he is under observation in hospital he does not complain much. It is somewhat significant, however, that he has a total acidity of 127 and free HCl of 60.

The operative methods at our disposal are:

1. *Local Excision of the Ulcer.*—This was employed on two occasions in the present series, and it was successful in neither.
2. *Cutting off the Gastro-enterostomy,* and the formation of a fresh anastomosis.—This was employed in Cases 1 and 4, two fresh anastomoses being necessary in Case 4, the gastro-duodenostomy done at the second operation being closed by ulceration. The ultimate result is moderately successful in both.
3. *Partial Gastrectomy.*—Employed on two occasions in the present series. Probable recurrence in one patient. The other operated on too recently for report. The drawback to this operation is that one is almost driven to an operation en-Y.

4. *Cutting off the Gastro-enterostomy, and Restoration of the Natural Channel.*—Where there is no pyloric stenosis, as in Case 2, this is the most satisfactory operation of all. Even where a plastic operation is necessary the ultimate outlook is fairly good. It is essential that the original ulcer, if still present, should be excised, and if this had been done in Case 3 I think that we should have avoided the stenosis which has gradually come on. The reason I did not do this was that the original ulcer was a perforating one, and the adhesions round the pylorus and duodenum were very dense.

Conclusions.

The conclusions one has arrived at are:

1. That operations for gastric and duodenal ulcers are to be regarded only as incidents in the treatment, and that diet, etc., and medical treatment should be persisted in after the operation for a long period.
2. That in addition to care in the technique it is preferable to use an absorbable suture material.
3. That any possible primary cause for the ulceration, such as an inflamed appendix or gall bladder, should be sought for, and if found removed.
4. That it is a mistake to occlude or otherwise deform the pylorus. This is unnecessary for the cure of the ulcer and deprives us of our best line of retreat should secondary ulcers form.
5. That when secondary ulcers have formed it is best to cut off the gastro-enterostomy and restore the natural channel if necessary by a plastic operation. The original ulcer, if still present, should be excised at the same time.
6. Where this is impossible and a fresh anastomosis is necessary operations of the Y type should be avoided.
7. Care is required after the operation for a long time.
8. That when one is operating for a perforated ulcer it is better to avoid gastro-enterostomy if possible, as so many of these cases recover completely without any recurrence of symptoms after suture of the perforation.

I have only touched on the subject of simple uncomplicated secondary ulcer to-night. The consideration of the various complications and their treatment would be much too wide a subject for the time at my disposal, and I have had none of these difficult cases under my care.

PROSTATECTOMY IN A CASE OF DIABETES INSIPIDUS.

BY

J. FINLAY ALEXANDER, M.D. CAMB.,

AND

F. S. KIDD, F.R.C.S. ENG.

The performance of prostatectomy in a case of diabetes insipidus does not appear to have been previously noted, and the presence of giant bladder, without evidence of renal or vesicle failure, is of interest.

Clinical History.

The patient, a grocer, aged 55, has had diabetes insipidus for at least twenty years. Probably he has had the condition longer, for twenty-five years ago he noticed that he was passing an unusually large amount of urine and that he was more thirsty. There is nothing in his past history to indicate the cause of the disease. He has led a very regular life, and his only excess has been bicycling. From the age of 18 to 35 he was accustomed to ride very long distances, often doing one hundred miles in a day, and riding all the test hills.

During the last twenty-five years the amount of urine passed has varied between 9 and 15 pints, the average amount in the twenty-four hours being 11 to 12 pints. He has suffered no discomfort beyond the inconvenience of having to micturate frequently and the excessive thirst. At one time he used to drink beer and whisky, but he found he required such a large amount of fluid that he soon gave up alcohol, and for many years has taken only plain water. In cold weather he drinks it warm, as he finds that this quenches his thirst more readily.

His general health is good, and he leads an energetic life. His weight has not varied for many years. He usually has a furred tongue, and is inclined to constipation. His blood pressure is normal (130 mm. Hg), but his pulse is always

rapid (90 to 100). He has had various spells of treatment, but no drug has had any effect in reducing the amount of urine. After a course of ergot he developed boils. Restriction of fluid merely increases the thirst, so for many years he has taken a glass of water, day and night, whenever he felt the desire; and, as his work is in his own shop, he has been able to carry on in spite of the frequent calls to pass water. He drinks over two gallons a day. The urine has for many years been pale and watery, acid in reaction, and with a specific gravity of 1002 to 1005. Occasionally there has been a faint trace of albumin, but never any sugar.

During the winter 1920-21 he first noticed pain in the suprapubic region, and at the end of the penis, on passing water, with increasing frequency and some hesitation. As the weather got warmer this trouble diminished, but he still had occasional pain in the penis, and felt that he was not emptying his bladder completely. Throughout the summer he was practically free from pain, but in the late autumn of 1921 the difficulty of emptying the bladder returned, with resulting increased frequency and pain. By the end of the winter the trouble had so much increased that he was not getting sufficient sleep, and was becoming quite worn out. The urine had for some time contained staphylococci and coliform bacilli, but as neither drugs nor vaccines improved the condition removal of the prostate was decided on.

Surgical Report.

Mr. Kidd's report is as follows:

"The patient was referred to me by Dr. Alexander on March 1st, 1922. He stated that for the last three months he had had great pain in the bladder region, a constant desire to pass water, which took a long time to come, and then only came in dribbles. He was in pain all the time; he had to get up at least eight times during the night; in fact, his condition was becoming unbearable.

"Abdominal examination showed that he had a giant bladder well up to the umbilicus. Rectal examination revealed considerable enlargement of the prostate gland of an adenomatous type. The urethroscope showed no stricture present. The Wassermann reaction was negative. X-ray examination showed no stone present, but a picture taken of the skull revealed hollowing and excavation of the pituitary fossa, suggesting that there was a cystic enlargement of the pituitary gland. . . . Ten to 12 pints of urine were passed in the twenty-four hours, which was very pale, specific gravity 1001, and contained no pus, albumin, nor sugar.

"I looked upon the giant bladder as the result of the diabetes insipidus, and not as a sign of advanced vesical and renal failure, as there were no clinical signs whatever of renal failure. Abandoning my usual custom in the case of giant bladder, I therefore resolved to pass a catheter for the purpose of renal function tests. Indigo injected into a muscle of the leg came through the kidneys in eight minutes, and in less than half an hour it had stained the urine a deep blue colour. This shows the value of time tests of renal function. The dilute urine made no difference whatever to the indigo test. The blood urea was 10.7 mg. per 100 c.cm. of blood, a very low quantity (the normal being 15 to 40 mg. to 100 c.cm. of blood). The exact significance of this I do not know, but the observation appears to be of interest.

"Urea concentration test = 1st hour—730 c.cm. of urine came through the catheter, specific gravity 1003, urea 0.4 per cent., total urea 2.92 grams; 2nd hour—770 c.cm. urine, specific gravity 1003, urea 0.4 per cent., total urea 2.93 grams.

"Cystoscopy showed a very definite but quite small middle lobe and two small lateral lobes projecting upwards into the bladder, with marked trabeculation of the bladder.

"Operation was performed in one stage on March 10th, 1922. The prostate was enucleated. It consisted of two small lateral lobes and a small vulvular middle lobe.

"After the operation the patient made 11 to 13 pints of urine a day, and it had to be collected in two large slop pails. He was passing all his urine naturally on the seventeenth day and went home soundly healed on the twenty-seventh day, passing 11 pints of urine freely with a good stream and without pain."

Five months after the operation the patient's condition is altogether satisfactory; his general health is very good, and he is free from all pain. He passes his urine with a good stream, though he states that towards the end of micturition he feels as if he had to use his abdominal muscles to help. He has, for him, good nights, only having to get up two or three times. In the day he can hold his water two and a half to three hours: he still passes 10 to 12 pints of clear watery urine in the twenty-four hours.

PARALYSIS OF THE FACIAL NERVE WITH HERPES ZOSTER.

BY

C. T. NEVE, F.R.C.S. ENG.,

ASSISTANT SURGEON, CROYDON GENERAL HOSPITAL.

THE facial nerve becomes paralysed more frequently than any other single nerve in the body, and yet the cause of this paralysis is in most cases unknown. In a certain small percentage it is due to inflammation of the wall of its canal in the bone, following on disease in the middle ear; or to trauma, operative or otherwise. Rarely it is caused by a central lesion, or is part of a polyncuritis, being then often bilateral. Again, it may accompany or follow a herpes of the face or neck, and is then generally supposed to be due to the inflammation of zona affecting the geniculate ganglion. But in the majority of cases no definite cause can be found; and, in default of a better explanation of the onset of this paralysis, exposure to cold is blamed. In view of the frequency with which this factor occurs in everyday life, it must always be considered unsatisfactory except as a merely contributory cause. From the nature of the case, material for pathological examination can be obtained but rarely. Inquiry must be made chiefly by clinical means.

It is the object of this article to show that herpes zoster affecting the geniculate ganglion is a much more frequent cause of facial paralysis than is commonly supposed, and that many of the cases where exposure to cold is blamed are due in reality to that micro-organism, at present unknown, which, attacking the posterior root ganglia of the spinal nerves, and the homologous ganglia of the cranial nerves, produces the interesting train of symptoms called herpes zoster.

Doncet (*Thèse de Paris*, 1936) collected 26 cases of herpes associated with facial paralysis. Analysis of these cases shows that the eruption appeared in the following situations: face, 27 per cent., neck 19 per cent., auricle 4 per cent., tongue and palate 19 per cent., face and neck 27 per cent., face, neck, and mouth 4 per cent.

Hearing was affected in 4 cases out of the 26—twice when the eruption was on the face only, once when on face and neck, once when on neck alone. Taste was diminished in 2 cases—associated once with herpes of the face and neck, once with herpes of face only. In 3 cases paralysis of one side of palate was noticed—once each with herpes of face, neck, and mouth. Three cases of herpes of the auricle are included, but in none of them was hearing affected.

No single one of these cases collected by Doncet showed all the symptoms which may be present in a case of the complete "syndrome of the geniculate ganglion." These are—as described by Ramsay Hunt in the following year—herpes, auricularis with facial palsy and affection of the auditory nerve.

It is evident from the consideration of these cases, and indeed from everyday clinical experience, that the symptoms which have been mentioned—herpes zoster of face, neck, ear, or mouth, paralysis of facial nerve, auditory nerve affection, diminution of taste—may occur grouped together in almost every possible combination. Facial paralysis may be associated with one or all of these other symptoms; no one of them is essential, neither herpes of ear, herpes of face or neck, nor affection of the eighth nerve.

If facial paralysis associated with herpes zoster is due to the inflammation of zona affecting the geniculate ganglion, those fibres whose affection causes the appearance upon the ear of the characteristic herpetic vesicles present in the complete syndrome of the geniculate ganglion often, indeed usually, escape. Thus in only 3 of the 26 cases collected by Doncet was the auricle affected. If this is so when the Gasserian ganglion is attacked together with one or other of its homologous ganglia, the Gasserian or posterior root ganglia of the second and third cervical nerves, why should it not be so when it occurs as an isolated lesion—that is, why should not facial paralysis be the sole symptom of an inflammation of the geniculate ganglion caused by the same virus which produces typical herpes zoster elsewhere?

Such an explanation fits in with the course and symptoms of a case of "idiopathic" facial paralysis. As in herpes zoster, there is often preliminary malaise; in children sometimes fever. Commonly, too, there is prodromal pain. In herpes zoster an enlargement and tenderness of the lymphatic glands draining the area of skin on which the eruption later

appears, but preceding that eruption, are almost invariable. I have not found such enlargement reported as occurring in facial paralysis, but it was present in a recent case of mine. The history of this case is as follows:

The patient, a male aged 21, previously healthy, on October 24th began to have pains behind the right ear and down the neck posteriorly on right side. He did not feel well; his throat was sore. On October 29th he felt a little tender lump in front of ear. October 30th: He woke up to find that his face was one-sided. When examined the same day he said he felt out of sorts; his ear felt "dull" and his tongue rough; he felt giddy. There was complete right facial palsy of the lower neurone type. One tender lymphatic gland in front of tragus of ear and one beneath lobule. No other glands palpable. Skin normal; auditory meatus and membrana tympani normal. Pupils slightly reddened, but no vesicles seen. No deafness to whisper or to acoumeter, but a low-toned tuning-fork was heard longer on affected side than on right. Taste normal; no nystagmus or Rombergism.

During the next few days his general condition returned to normal, and auditory and sensory symptoms disappeared. Facial paralysis persisted, showing only slight improvement after two months. The affections of taste and hearing in this case were so slight that a less observant patient might not have remarked on them.

It seems probable that in many cases of apparently uncomplicated facial paralysis there will on inquiry be found some slight symptoms pointing to an affection of the geniculate ganglion, and leading one to suppose that the paralysis is a neuritis due not to exposure to cold but rather to inflammation in the geniculate ganglion, the facial fibres suffering severely, while those which carry the sensation of taste—the pars intermedia—and those of the adjacent eighth nerve have almost, if not completely, escaped.

DYSTOCIA DUE TO GIGANTIC FEMALE FOETUS.

BY

E. L. MOSS, C.M.G., M.C.,

MAJOR, R.A.M.C.

A WOMAN, aged 22, was admitted to the Louise Margaret Hospital, Aldershot, on March 22nd, 1922, with oedema of the legs and face, and a bunion. Her periods had been regular up to the last one, which began on July 25th and ended July 30th, 1921. Quickening was felt about the first week in December. She had had one normal confinement two years before, when a healthy female child weighing 10 lb. was born. The mother and father are both six feet in height.

On admission the patient had marked oedema of face, lower abdomen, vulva, and legs. The abdominal enlargement was much greater than usual, and suggested multiple pregnancy and hydramnios. On palpation the uterus was so tense that the only foetal part distinguishable was the vertex, and even this was difficult to define. Only one foetal heart was heard, on the right side, between the umbilicus and anterior superior spine. The fundus reached to the ensiform cartilage. A tentative diagnosis of hydramnios and multiple pregnancy was made.

The pelvic measurements were as follows: Intercristal 12 in., interspinous 10½ in., external conjugate 8½ in., inter-tuber ischii 4½ in. By vaginal examination the promontory could not be reached. The blood pressure was 160 mm. of mercury on admission, but after three days it fell to 130 mm.

The urine contained a heavy cloud of albumin, but no pus cells or renal casts; ammonia nitrogen 0.23 gram, urea nitrogen 0.7 gram, a slight trace of acetone and diacetic acid. On culture it yielded a coliform organism.

The urinary condition and oedema cleared up satisfactorily under treatment with vapour baths, saline aperients, and a course of potassium citrate, followed by urtropine and acid sodium phosphate (given separately), combined with light diet.

The patient was kept under observation in hospital, and on April 26th, at 8.15 p.m., the membranes ruptured. Pains began at 9 p.m. The vertex was felt presenting in the R.O.A. position. Pains continued regularly, but not very strong, and at 3 a.m. on April 27th the os was fully dilated. After one and a half hours in the second stage, as there was no advance of the head, which was engaged in the brim, and as the foetal heart sounds were still audible, anæsthesia was applied under general anæsthesia, and the after considerable difficulty. The outlet between the paws was very uncut owing to its large size. A loop of cord feebly pulsating could be felt above the head.

Obstruction to the further birth of the child occurred at this stage owing to the shoulders being wedged across the brim of the pelvis in the right oblique diameter. Attempts at digital traction with the finger in the posterior axilla failed. A blunt hook was therefore used, with the result that the shoulders were brought sufficiently low down for the arms to be disengaged and delivered alternately. The child was stillborn. The perineum was ruptured, but the tear did not extend through the sphincter ani. The

placenta followed forty minutes later and appeared perfectly healthy, but weighed 4 lb.

The puerperium was uneventful. The patient was sitting up and well on the twelfth day.

Particulars of the Child.

Weight (verified by separate weighing machines, and observers)	24 lb. 2 oz.
Length—vertex to heel	35 inches.
Length of spine	15½ "
Bis-acromial	8½ "
Length of arm	13 "
Length of foot	5½ "
Circumference of thigh	10 "
Circumference of forearm	7 "
Bi-trochanteric	6 "
Head circumference	19 "
Bi-mastoid	4½ "
Bi-malar	4½ "
Suboccipito-bregmatic	5½ "
Suboccipito-frontal	6½ "

The post-mortem examination was confined to examination of the brain. The bones of the vertex were harder and exhibited a greater degree of ossification than usual. The anterior fontanelle was smaller than usual. On opening the skull the dura was firmly adherent to the calvarium, and the brain was so soft and flaccid that it could not be removed intact; it was put into formalin solution, but after twenty-four hours had fallen to pieces. A portion of the pithary was saved and examined, but merely exhibited undue vascularity of the pars anterior.

The foetus is preserved in the Museum of the Royal Army Medical College, Millbank, London.

Induction of labour or Caesarean section would have been considered had it been possible to diagnose a foetus of such large size. Pelvimetry had shown that the maternal passages were abnormally large. The difficulty was that the uterus was so tense with excessive liquor amnii and the large foetus that its contents could not be palpated clearly. It was not reasonable to anticipate trouble with a pelvis of this size, especially as we had in mind the probability of hydramnios and twins, and knew that a 10 lb. baby had been born without trouble previously.

Cleidotomy was not performed because at the stage when it suggested itself as a means of overcoming the difficulty with the shoulders it was still hoped to get a living child.

Memoranda:

MEDICAL. SURGICAL. OBSTETRICAL.

A CASE OF CONGENITAL PYLORIC STENOSIS.

THE occurrence of congenital pyloric stenosis in female children is, I believe, of sufficient rarity to be worthy of note.

A colleague called me into consultation upon a marasmic female infant aged 3 weeks. It was a second child, the first being a healthy boy, and labour had been normal. The mother appeared perfectly healthy and was feeding the child herself.

The child commenced to vomit its feeds when about 10 days old; at first this was so slight that it was considered to be a mere regurgitation caused by indigestion. During the next few days the vomiting became more and more frequent, and the child began to waste away. The vomit was greenish, but without success. The child was really projectile in type, even the smallest feeds of albumin water being returned. These were the conditions when I was called in; in addition there were scattered rales over the bases of both lungs.

A feed was given to the infant in our presence, and within a minute well-marked slow peristaltic waves could be seen passing across the abdomen from left to right in the region of the stomach. This peristalsis was apparently painless. Shortly afterwards the vomiting began and was projectile in type. A thickening could be felt in the region of the pylorus. The stools up to this time had been normal, showing no signs of failure of digestion, but the apparent constipation now present was another point in the diagnosis.

Given these symptoms—namely, projectile vomiting, visible peristalsis in the gastric region, palpable thickening in the region of the pylorus, apparent constipation, and marked wasting—a diagnosis of congenital pyloric stenosis was made. I am indebted to Dr. Frederic Still for the following notes giving details of the treatment:

"The operation was performed by Mr. Tyrrell Gray, after repeated subcutaneous saline infusions had produced a slight rally. I was watching for the moment when it might be just possible to operate, for the child was in an almost desperate condition when I first saw it about eighteen hours before operation. I was not only extremely feeble and somewhat blue, but there were sharp rales all over the bases of both lungs. We took advantage of the temporary rally, and Mr. Gray did a Stammstedt operation—that is, a simple longitudinal incision through the muscular layer of the pylorus without cutting through

the mucosa. The child stood the operation well, and with further subcutaneous infusions rapidly gained strength, and has since kept down its breast-milk feeds well."

The infant has progressed satisfactorily, and has gained 1 lb. 2 oz. since the operation three weeks ago. This gain is perhaps less than might be expected, but is to be attributed chiefly to the deficiency of breast milk after the temporary weaning.

According to statistics, the condition is rare in female children, 80 per cent. of cases occurring in boys (Garrod, Batley, and Thursfield, *Diseases of Children*), and more commonly in first children.

AUTOGENOUS VACCINE IN PUERPERAL FEVER.

I wish to bring before country practitioners the efficacy and great assistance of autogenous vaccines in the case of puerperal fever. Lately I had a case as follows:

The birth was by means of forceps delivery with small tear in the perineum. This was stitched. Four days later, after having been given castor oil, the patient's temperature rose and the lochia ceased. Immediately intrauterine douching (twice daily) was commenced and salol and hexamine were administered every four hours. This treatment went on for five days with little or no success. The pulse ran up to 120–130. The temperature was 105° in the morning and 101° in the evening on an average. On the sixth day 20 c.c.m. of a well-known make of stock polyvalent anti-streptococcus serum was given, with no result. On the next day 10 c.c.m., similarly with no result. The heart condition now began to show slight indications of commencing endocarditis.

I examined a loopful of the discharge from the cervix and identified coliform organisms and streptococci. I then sent a loopful of this discharge for the preparation of an autogenous vaccine.

As the action of the heart was becoming weak, heart stimulants were now used, chiefly digitalis, with caution, for fear of embolism, but even in moderately large doses the result was disappointing. Antipyretics were of little use, although small doses of aceton helped a little.

Four days after the dispatch of the specimens (with all due credit to the Royal College of Physicians' laboratory, Edinburgh) I received the autogenous vaccine, each cubic centimetre of which contained 50 million coliform organisms and 50 million streptococci. I gave 1/10 c.c.m. immediately, and progressively doubled this dosage every twenty-four hours, till the patient was receiving approximately 1 c.c.m. every twenty-four hours. The results were marvellous. The temperature fell as if by magic, and on the sixth day after the commencement of treatment by the autogenous vaccine the endocarditis had cleared up and the temperature was normal. Recovery was now well established. The vaccine was still continued for some days (1 c.c.m. every twenty-four hours).

I wish to draw attention to the fact of the absolute failure of the stock serum in this case; in fact, after administration serum manifestations caused the patient's condition to become worse.

Cowdenbeath.

JOHN VEITCH, M.B., Ch.B.

ELECTRICAL TREATMENT IN TUBERCULOUS DISEASE.

IN THE BRITISH MEDICAL JOURNAL of June 4th, 1921 (p. 812), I described experiments I had performed for the destruction of bacilli by electricity. Since that date I have treated an obstinate case of tuberculous colitis by galvanism with an excellent result.

The patient, aged 26, was sent to me by his doctor, who suggested that as I had destroyed staphylococci and *B. coli* by an electrical current it might be possible to kill the tubercle bacillus in the same way.

Nearly two years before I saw the patient he had mild diarrhoea and passed blood and mucus. He had previously had an empyema which had been operated upon and the wound healed. The diarrhoea was continuous and did not respond to drugs. Wasting was marked and the temperature high. An autogenous vaccine had been prepared and a course given with no apparent improvement in the symptoms. Later (nine months before I first saw him) appendicectomy was performed and daily the colon was washed out with saline, silver nitrate, and sometimes Dakin's solution, other antiseptic

drugs being administered by mouth in turn. Still no marked improvement was shown.

I first saw the patient in September, 1921, when he was passing a large quantity of blood and mucus. He was pale and thin. For half an hour three times a week I passed a galvanic current through the abdomen, making him lie on one large pad and placing the other on the anterior abdominal wall.

In April, 1922, he was passing one stool a day and no blood and very little mucus. The weight had increased by several pounds, and the patient himself admitted he was feeling better than he had ever done in his life. At the end of May treatment ceased, and he returned to his laboratory work.

I saw him again last month and he said he was perfectly well, was above his normal weight, and was passing normal stools with no blood or mucus.

Brighton.

Reviews:

OPIUM AND COCAINE IN INDIA AND BURMA.

Is a small book entitled *Drug Smuggling and Taking in India and Burma* Mr. ROY K. ANDERSON, superintendent of the Burma Excise Department, tells the ugly story of the abuse of opium, morphine, and cocaine with reasonable fairness, though the writer to some extent disarms criticism by stating at the outset that he is not an authority on the subjects dealt with. He has, at any rate, had very intimate acquaintance with the smuggler and his tricks through his knowledge of customs and excise and the elaborate system of preventive men, as well as paid informers whom he has been compelled reluctantly to employ.

He relates the history of the introduction of opium into India, presumably by the Arab conquerors in the eleventh century; their faith forbade alcohol, but they found solace, it is suggested, in opium and Indian hemp, much as the aborigines of Peru indulged in the leaves of the coca plant. Mr. Anderson is prepared to justify "the moderate use of opium," without venturing on a definition of that much abused word "moderate," and seems inclined to condone the chewing of coca leaves. Nevertheless, he is emphatic in his condemnation of the "awful results of this damnable traffic in drugs"; he asserts that morphine is abused by hundreds of thousands, and speaks of the results of the indulgence in cocaine as "truly deplorable." He appears to regard the smoking of opium as less injurious than eating opium, thus differing from the official view propounded in the recently published *Truth about Indian Opium*, which sought to justify the ingestion of the drug by natives while condemning smoking as "essentially a social vice."

Mr. Anderson will probably find many to agree with him in the view that the gin palace is more antisocial in the distress it occasions than is the opium den, but the interesting illustrations which he supplies are sufficient to confirm his statements as to the disastrous effects on the physical, mental, and moral condition of the victims of opium or coca. Indian hemp, he holds, does not get a similar hold upon its addicts, and the habit is given up with less difficulty. Mr. Anderson confirms the allegations which have been made as to the extent of smuggling of morphine derived from Great Britain, the Continent of Europe, and Japan, carried on by ships' crews; as much as 500 oz. have been seized in one haul, and for every ounce seized he believes a pound goes in undetected. The author entirely approves of the Dangerous Drugs Act passed here in 1920 and calls for international co-operation in controlling this hateful traffic. No more humanitarian labour could at the present time engage the activities of the League of Nations.

PSYCHOLOGY AND PSYCHOPATHOLOGY.

MANY of the more popular and elementary books on the "new psychology" give the impression that their writers are somewhat lazy in their views themselves, and this is perhaps the reason they are apt to mystify rather than illuminate their readers. It is therefore a pleasure to read *The Psychology of Medicine*,² by Dr. T. W. MITCHELL, who has not only made a close study of the development of medical psychology during

¹ *Drug Smuggling and Taking in India and Burma*. By ROY K. ANDERSON, F.R.S., Superintendent, Burma Excise Department. Calcutta and Simla: Thacker, Spink, and Co. (Copies may be obtained from W. Thacker and Co., 2, Cecil Lane, London, E.C.4.) 1922. (Cr. 8vo, pp. 141; illustrated, 7s. net.)

² *The Psychology of Medicine*. By T. W. MITCHELL, M.D. London: Methuen and Co. 1921. (Cr. 8vo, pp. vi + 167. 6s. net.)

the last twenty years, but has the gift of presenting his subject-matter in a particularly clear, orderly, and balanced manner. After an introductory chapter in which the aims and scope of the book are indicated, the phenomena and theories of dissociation, repression, the unconscious, psychoanalysis, dreams, the neuroses, and psychotherapeutics are described. In a chapter on the prevention of neurotic illness a general account is given of the environmental factors which exert an unfavourable influence upon the emotional development in childhood, but the author points out that the more we know of the complexity of the conditions on which the occurrence of a neurosis depends the less sanguine are we of being able to prevent its development by avoiding any one of them. The book may be recommended to the student of psychological medicine who is desirous of obtaining an adequate preliminary knowledge of the various schools of psychotherapy. The title of the volume is perhaps somewhat misleading, as it suggests a much wider theme than the author proposes to consider.

In the treatment of nervous cases Dr. WILLIAM BROWN believes it possible to have a sound system of psychotherapy which combines mental analysis with suggestion and auto-suggestion. He has developed this view in a small volume entitled *Suggestion and Mental Analysis*³; it is written on popular lines, and deals more particularly with the theory and practice of suggestion as taught by M. Coué, whose recent demonstrations in this country attracted a good deal of notice. Dr. Brown expresses his appreciation of what he describes as M. Coué's clear and penetrating insight into the facts of suggestion, but he points out quite truly that medical men have employed for many years the methods of treatment which M. Coué advocates, and that they have been in a position to apply them with more understanding because of their knowledge of the facts of mental and physical disease. Having given some account of suggestion, mental analysis, the psychoneuroses, and hypnosis, Dr. Brown suggests that in the causation of functional nervous conditions two general factors are at work—mental conflict and bad auto-suggestion. He holds that as the result of mental conflict the mind is weakened; there is a weakening of mental synthesis, with the result that the individual shows a tendency to be readily overwhelmed by emotion and readily carried away by certain ideas if supported by certain feelings. It is the existence of these two factors which, in the author's experience, necessitates a combined method of treatment. The mental conflict is resolved by mental analysis, and the bad habits of mind resulting from bad auto-suggestion are treated by counter-suggestions communicated to the patient while in a state of somnolence. Dr. Brown maintains that when the patient has been treated along these lines for a few hours he is brought into a position to carry out the practice of auto-suggestion. Dr. Brown does not write from the strictly scientific point of view; he quite frankly insists on a religious attitude as part of the necessary equipment of the psychopathologist, and introduces the phraseology of mysticism into his suggestive therapy. These views are rather perplexing; we should have thought it particularly desirable for the psychopathologist to maintain an impersonal and objective outlook, and to avoid any tendency to approach his clinical material through the medium of his personal attitudes and desires, as otherwise he will find himself involved in functions which are outside the sphere of the doctor and will inhibit his usefulness in the investigation of disease and its causes. We do not doubt the value of the form of therapy which Dr. Brown advocates, though some of his theoretical views would seem open to question; suggestion is a biological process which exerts a considerable influence on mental development, and it is quite to be understood that, when applied with the precision which previous mental exploration makes possible, it may have considerable therapeutic value.

DIABETES.

THE publishers of the interesting collection of books dealing with the diseases of middle age may be congratulated on the practical value of directing attention to the special danger of the fifth decade of life. One particular danger besets most men and some women at this age—namely, the tendency to eat too much and to exercise too little. It is the age when we begin to pay for success in our business or profession by

³ *Suggestion and Mental Analysis: an Outline of the Theory and Practice of Mind Cure*. By W. BROWN, M.A., M.D. (Oxon.), D.Sc., London: University of London Press, Ltd. 1922. (Cr. 8vo, pp. 165. 3s. 6d. net.)

being able to indulge in the pleasures of the table and by driving in a motor car instead of walking. At a time when we need nourishment the least we can often afford it best—or rather our bank balance can afford it, whereas our metabolic exchange may crash. Dr. LECLERCQ points this out clearly in his book on diabetes.⁴ Since 1911, he reminds us, he has been insisting that glycosuria is the result of a disturbance of protein metabolism rather than of carbohydrate excess. Without going so far as to say that he overestimates the importance of the protein origin of the blood sugar in diabetes, we think Dr. Leclercq is not supported by facts when he rejects carbohydrate excess as a factor in the production of diabetes. Colonel McCay's observations in India cannot be ignored quite so completely. The view that Dr. Leclercq gives of the physiology of the liver and its functions is admirable, and so is his summary of the whole experimental data bearing on sugar production and elimination. But when he comes to expounding his own theory that diabetes is a defensive mechanism whereby many toxic products of erratic protein metabolism are transformed into sugar for the purpose of harmless excretion we feel he is largely and boldly speculative. The conjunction of protein disturbance with that of carbohydrate metabolism has rightly been insisted on by Marcel Labbé, and it is fully realized how seriously this conjunction aggravates an error of mere carbohydrate metabolism. There are, however, grounds for not accepting the author's suggestion that diabetes can be averted in the early stages by restricting protein foods, especially meat, and increasing the carbohydrate intake. He makes an arresting suggestion for the treatment of diabetic coma and uraemia; it is that since subcutaneous injection of phloridzin causes a glycosuria with hypoglycaemia, this drug might rid the blood of the toxic substances responsible for diabetic coma and uraemia. Unfortunately, Dr. Leclercq has not sufficiently tested his theory by practical trial. In fact, whilst the whole book is full of stimulating ideas, some of those ideas would have been better employed as the basis of careful experimental research. John Hunter's greatest contribution to the art and science of medicine was his advice to Jenner, "Don't think, try."

In his general preface to the library of medical knowledge he is editing Dr. ARRHÉ wins our whole-hearted approval when he explains that the series of short monographs on special subjects is written in the vernacular—that is to say, in everyday French, technical words being used as little as possible and then only after what they mean has been explained. Medicine, the editor continues, is no longer the secret art of former times; his aim is to free medical writing from the cabalistic formulas inherited from our forefathers that may have matched the "long robe" and the gold-headed cane well enough, but now serve only to make obscure the subjects treated. In the volume before us Dr. RATHERY has condensed into small compass present-day views about diabetes. The sum of our real knowledge might have been still more briefly expressed. Even in this little book room is found for a good deal of highly speculative theory. We find the statement that "arthritis" provides many examples of disturbed nutrition. Dr. Rathery confesses that no one can define "arthritis," but he agrees that it represents an indispensable idea. Indispensable ideas are great stumbling blocks to scientific progress. Dr. Rathery succumbs to the ruling passion for classification, and offers us a choice of three fundamental varieties of diabetes—a simple, a consumptive, and a mixed form. "Diabète consomptif" strikes us as a term devoid of all value or justification; the editor has failed here in his aim at simplifying and clarifying the language of medicine. On the whole the book is not one that we can recommend to English readers.

THE MAYO CLINIC.

THE thirteenth volume of *The Collected Papers of the Mayo Clinic*⁵ (Rochester, Minnesota) contains 108 articles contributed by seventy-six of its indefatigable workers, headed by the famous brothers, W. J. and C. H. Mayo. The contents, already published elsewhere, though sometimes in rather

inaccessible periodicals, impress the reader with an admiration for the activity of this great graduate medical centre.

The articles are arranged under nine headings dealing with the alimentary, urogenital, endocrine, blood, cutaneous, and nervous systems, the head, trunk, and extremities, technique, and general subjects. The first contains the largest number (23) of articles, and among them attention may be called to Dr. R. A. Carman's "Errors in the Roentgenologic diagnosis of duodenal ulcers," Professor E. C. Roseow's "Focal infection and elective localization of bacteria in appendicitis, ulcer of the stomach and pancreatitis," and to Dr. H. R. Hartman's account of hydrochloric acid in gastric carcinoma, showing that achlorhydria, which is so generally regarded as an essential diagnostic sign, was present in rather less than 50 per cent., and a normal or hyperacid value in more than 25 per cent., of 631 cases. In the course of an address dealing with carcinoma developing on gastric ulcer, which at one time seemed to occur with rather startling frequency at the Mayo clinic, Dr. C. H. Mayo says that it is now advisable to drop the percentage basis, and in speaking of carcinoma generally, predicts that from the recent developments of serum, endocrine, x-ray, and radium treatment, surgery will become an adjunct to these methods instead of the major treatment. In the section on urogenital diseases Drs. Bumpns and Meisser continue their experimental study of foci of infection in pyelonephritis, and show that infection of the kidney may often be due to focal infections in the teeth, tonsils, and elsewhere harbouring streptococci which have a selective affinity for the urinary tract, and that the colon bacillus, so commonly found and regarded as responsible, is of secondary importance.

There are two reports by Dr. Bumpns and by Dr. V. C. Hunt on submucous ulcer of the bladder, and there are papers dealing with functional tests of the kidney. Professor Reginald Fitz deals with the much neglected subject of the prevention of some cases of chronic nephritis—namely, by the removal of septic foci in the teeth and tonsils. Dr. W. M. Boothby writes on the basal metabolic rate in hyperthyroidism, Dr. L. B. Wilson on the pathological classification and diagnosis of malignant tumours of the thyroid, and Dr. William Mayo on splenectomy in splenic anaemia and Banti's disease. Professor E. C. Roseow and Dr. Winifred Ashby's report on focal infection and elective localization in the etiology of myositis is based on the examination of 28 cases in six years, and the injection of pus or streptococci from the tonsils or teeth into rabbits; in 24 cases the streptococcus was found to have an elective affinity for the muscles. Among the general articles there is an especially interesting address by Dr. William Mayo, "In the time of Henry Jacob Bigelow," delivered, on his receipt of the Bigelow medal, to the Boston Surgical Society. In conclusion, this veritable storehouse of information on the recent advances in medicine has been admirably edited by Mrs. M. H. Mellish.

DISEASES OF THE DIGESTIVE SYSTEM.

THE twenty lectures contained in the fifth series of Professor MAURICE LOEPER'S *Leçons de pathologie digestive*⁶ were delivered partly in the course of general pathology in the Medical Faculty of Paris and partly at the Tenon Hospital, and deal both with the pathology and with the clinical and therapeutic aspects of disease of the alimentary tract. The subject-matter is interesting for its variety as well as for the views expressed. The mechanism of the nervous manifestations of intra-abdominal disease receives much attention, and illustrations of structural change in the vagus in ulcer and in malignant disease of the lesser curvature of the stomach are given, cancerous infiltration of the nerve explaining cardiospasm in such cases of gastric carcinoma. In another lecture, on painful crises in the course of malignant disease of the oesophagus, in one form of which angina pectoris is imitated, infiltration of the vagus and phrenic nerves is described. Similarly, in the discussion of coeliagia, neuritis in dysentery and cancerous invasion of the nerves in the mesentery is figured. Coeliagia is divided into the primary forms, as in tabes, syphilis, and syringomyelia, and the forms secondary to various causes, visceral and toxic, such as lead; an interesting example of the latter condition is described in an oxalric patient with crystals of oxalic acid in the semilunar ganglion. The importance of the estimation of pepsin in the gastric juice, the significance of

⁴ *Le Diabète et son traitement*. Second edition, corrected and enlarged. By Dr. Arthur Leclercq. Les maladies de la cinquantaine. Tome II. Paris: Gaston Doin. 1922. (Demy 8vo, pp. 268. Fr. 15.)

⁵ *The Collected Papers of the Mayo Clinic, Rochester, Minnesota*. Edited by Mrs. M. H. Mellish. Vol. xiii, 1921. Philadelphia and London: W. B. Saunders Co. (Med. 8vo, pp. xiii + 1318; 392 figures. 62s. net.)

⁶ *Leçons de pathologie digestive* (cinquième série). Par Professor M. Loeper. Paris: Masson et Cie. 1922. (Demy 8vo, pp. xii + 313; 55 figures. Fr. 15.)

pepsin in the urine, and the proper method of administering pepsin by the mouth form the text for three other lectures. The cachexia of gastric carcinoma is correlated with an excess in the blood serum of toxic albuminous bodies produced by a proteolytic ferment resembling crepsin, which is secreted by the growth; as a defensive measure antiproteolytic bodies are manufactured in the serum, and as this process is favoured by the administration of trypsin this means of treatment is advocated. Evidence is brought forward to show that the grave anaemia of gastric cancer is due to the haemolytic effects of albuminous and lipid bodies in excess in the serum, and to counteract this the administration of cholesterol or more simply of yolk of egg is recommended. Other chapters are devoted to plastic linitis (carcinomatous) of the pelvic colon, the gastric symptoms of gall stones, phlegmonous gastritis (with the details of a case due to gassing), and the dietetic treatment of gastric disorders; but enough has been said to show the stimulating character of Professor Loeper's work.

NOTES ON BOOKS.

PHARMACISTS and dispensers must have a ready memory for a great number of facts such as the nature of the active constituents in galenical compositions; their proportions in compounded articles, and the magnitudes of medicinal doses. These must for the most part be acquired by simple effort of memory. Were this not the case there would have been little excuse for the production of GWYNETH PENNETHORNE'S *Guide to Assistant's Examination in Materia Medica and Pharmacy*,⁸ for the contents of the volume consist chiefly of those memoranda in their briefest form; the work can hardly be said to teach the subjects of its title on an educational plan. Something may perhaps be said for beginning a subject with the facts to be memorized and taking up a more rational scheme of study afterwards. Thus applied this book may be useful since its contents are substantially free from inaccuracy. It has, moreover, a budding element of merit above that of such books as are intended to do no more than circumvent the tests expected from the examiner; a number of hints given on methods of dispensing are well conceived. A moderate addition of explanatory matter would have greatly enhanced the value of the book. For example, the article on milk sugar contains the sentence, "It is used as a diluent of powerful drugs," but nothing is said to indicate the properties which render milk sugar the most suitable of materials for that purpose, although one or two short sentences would have sufficed. Obviously a more complete treatise will be required by those who are to escape the dangers of possessing only a little knowledge, but an edition of this work interleaved with blank pages for the notes of the user might be found serviceable by a considerable number of students of materia medica and pharmacy.

*Dream Fairies*⁹ is the title of a collection of enjoyable verses written for children by Dr. T. WILSON PARRY, and illustrated in black and white by Mr. Gerald Aylmer. The little volume is redolent of the English countryside, and should prove a delight to the innumerable children who love birds, butterflies, brooks, frogs, flowers, and fairies. Mr. Aylmer's apt sketches really illustrate the text, and he shows an excellent sense of design in his pen-and-ink drawings. Personally, we liked his pictures of little girls (as on p. 4) better than his fairies, but we confess that a child who was shown the drawings greatly preferred the fairies to the children.

Under the title *Massage and Exercises Combined*,¹⁰ a Mr. ALBRECHT JENSEN of New York has published an illustrated account of a course he has devised of mild gymnastic exercises, combined with self-massage and breathing exercises. The book is addressed rather to the general public than to the medical profession, and contains a number of superfluous adornments such as a display of high-sounding adjectives on the title-page and a portrait of the author on art paper as a frontispiece. The exercises themselves, however, are not without merit, being simple and requiring no undue straining nor any gymnastic apparatus.

ERRATUM.—The price of Dr. L. Emmett Holt's *Diseases of Infancy and Childhood*, published by Messrs. D. Appleton and Co., is 35s., not 6s., as by a clerical error was stated in our issue of September 25rd at page 566.

⁸ *Guide to Assistant's Examination in Materia Medica and Pharmacy. Apothecaries' Hall.* By Gwyneth Pennethorne. With a Preface by P. A. Ellis Richards, F.I.C., F.C.S., London: Baillière, Tindall, and Cox. 1922. (Fcap. 8vo, pp. xi + 566. 6s. net.)

⁹ *Dream Fairies.* By T. Wilson Parry. London: Simpkin, Marshall, Hamilton, Kent, and Co. 1922. (Demy 4to, pp. 34; illustrated. 2s. 6d. net.)

¹⁰ *Massage and Exercises Combined.* By A. Jensen. New York: A. Jensen, Box 73, G.P.O., New York City. 1920. (Sup. roy. 8vo, pp. 23; 85 illustrations. 2.50 dols.)

THE ORGANIZATION AND FINANCE OF VOLUNTARY HOSPITALS.

SIR NAPIER BURNETT'S REPORT.

SIR NAPIER BURNETT, Director of Hospital Services for the Joint Council of the Order of St. John and the British Red Cross Society, has just published his third annual report¹ of the voluntary hospitals in Great Britain, excluding London. This report contains the result of his examination of the statistics of the voluntary hospitals for the year 1921. It deals not only with the financial status of the hospitals, but also with the quality of their work and their relative efficiency. As the hospitals in the London area are under the supervision of the King Edward VII Hospital Fund they are not included.

The object of these annual reports is thus twofold—namely to present to the public detailed information regarding the financial position of the voluntary hospital system, and to assist hospital governors and administrators with information whereby they may ascertain how their hospital position compares with the group averages of other comparable institutions. As regards the financial side of the problem, it is interesting and encouraging to note that in the year under review the majority of the provincial voluntary hospitals were able to pay their way for the first time since the war. A prices were high at the beginning of 1921 and unemployment was rife during the latter part of the year, the hospitals may now look forward with rather more confidence to the future and it is expected that the figures for 1922 will show an even better position.

Classification of Hospitals.

The classification adopted in the present, as in previous reviews is according to size or the number of available beds the hospitals are further grouped into general and special and the latter are subdivided according to the age and sex of patients and to the nature of the ailments treated—for example, eye or ear and throat hospitals. Sir Napier Burnett considers, however, that such classification is unsatisfactory and that a new method of grading hospitals is required. Thus, two hospitals with the same number of beds show in their annual reports that one has cost 50 per cent. more than the other, and the impression produced when they both appeal to the public for support may be that the one hospital is extravagant and inefficiently administered in comparison with the other. The true position may be, on the other hand, that the hospital showing the higher cost is really the more economical, in that it is supplying a much fuller service to the public than its neighbour. One, for instance, may be provided with a full range of special departments, including bacteriological and pathological laboratories for the investigation of the causation of disease, while the other hospital merely acts as an infirmary for sick folk and has few facilities for the study of disease. Such hospitals are not at all comparable from the point of view of service rendered to the community, and yet as they are graded at present, according to size, the public have not the knowledge of how to discriminate.

Sir Napier Burnett considers that hospitals may be graded according to the quality of the work that they do and the facilities they provide for carrying out such work. The group of hospitals known as teaching hospitals, in that they are associated with medical schools, should, in his opinion, be graded as a group apart from all other hospitals. Excluding the teaching hospitals, he suggests that other hospitals could be graded into classes A, B, and C, according to their general standard of equipment and laboratory facilities, etc. On such a basis the subscribing public would have the knowledge to enable them to appreciate why the class A hospital is necessarily more expensive than one in class C.

It may be remembered that a few years ago the American College of Surgeons decided to carry out a survey of the hospitals in the United States and Canada with 100 or more beds. Of these there were 697, and the object of the survey was to ascertain how many of the hospitals conformed to the minimum standard of efficiency laid down by the College—namely, the keeping of proper clinical records by the

¹ *Third Annual Report on the Voluntary Hospitals in Great Britain (excluding London) for the Year 1921.* By Sir Napier Burnett, K.B.E., M.D., F.R.C.S., F.R.C.P., with an introductory note by the Hon. Sir Arthur Stanley, G.B.E., C.B., M.V.O. Published by the Joint Council of the Order of St. John and the British Red Cross Society, 19, Berkeley Street, London, W.1. Price 2s. 2d.

hospitals, an organized staff of surgeons, and adequate laboratory facilities. In 1918-19 only 89 of the 697 hospitals attained this minimum standard; in the next year 198 attained the standard; in the year afterwards 407 met it, or agreed to meet it; and in 1921, when the report was published, it was hoped that the number would be nearly 550. It was evident, therefore, that the adoption of a minimum standard gave a considerable impetus to the improvement of the medical service within the hospitals, although the American College had no authority to impose any standard on any hospital, except the authority of the ideal. There is no doubt that the average standard of the provincial hospitals in England is at present high, but there is no reason why it should not be higher still. If, therefore, the Joint Council takes up the improvement of the scientific and professional standard of the provincial hospitals as part of its work it will confer considerable benefit upon the community.

Hospital Income and Expenditure.

Taking Great Britain as a whole, excluding London, details of patients were received from 642 voluntary hospitals—that is to say, from 88 per cent. of the total hospitals—with 39,973 available beds. It was found that 2,545,055 individual patients were treated during 1921 at a total cost to the hospitals of £5,275,176. Towards this expenditure the hospitals received £4,854,661, leaving a deficit on the year's working of £420,515. One-third of the total ordinary income of the hospitals was derived from workmen's contributions and patients' payments. While in 1920 44 per cent. of the provincial hospitals were able to show a financial surplus on the year's work, in 1921, despite the financial depression and the extent of unemployment, the number of hospitals with a balance on the year's working increased to 51 per cent. As was the case in 1920, only one group of hospitals—the small or cottage hospital group—showed an excess of income over expenditure, but it was also the only group that showed an increase of expenditure over that for 1920. It is probable, however, that these small hospitals receive the benefit of the reduction in the price of hospital commodities some time later than the larger hospitals, who are able to buy in greater quantities—an argument in favour of collective buying. Taking in review the figures for the past three years, there is gratifying evidence of the progress that is being made by the hospitals to improve their financial position. An increase of ordinary income was shown in the three different groups of hospitals—that is, in hospitals of varying bed capacity. The small or cottage hospital group fell back in income last year by £2 per available bed as compared with the previous year. Taking the hospitals as a whole, the figures show the deficit per available bed has fallen from £15 in 1919 to £10 in 1921. The total amount of the accumulated debts to the banks of the provincial hospitals in England and Wales amounts to £681,368, while the invested funds of the hospitals, including both realizable and non-realizable or trust funds, amount to £5,913,943.

Hospital Provision for Patients of Moderate Means.

In Sir Napier Burnett's view the hospital provision for patients of moderate means is probably the most urgent problem calling for solution in the hospital world. The hospital of to-day is a much more expensive institution than its predecessor of twenty years ago, in a large measure because of the many advances that have been made in scientific medicine and surgery during those years. To keep abreast of these developments elaborate and expensive apparatus is required, and new departments have to be established to meet the demands of specialists. The benefits of these scientific advances are now available for the poor in the public hospitals and for the rich in private hospitals, but those with moderate means, who are debarred from the private institution because of the cost and yet are above the income limit for admission into the public hospital, suffer a real hardship in being unable to participate in the benefits of modern hospital scientific resources. Sir Napier Burnett believes that the full solution of this problem will not be reached until the medical profession come to realize that the payment of a hospital medical staff is really centred in the question of the provision of hospital beds for this class of the community. He makes an appeal to the medical profession to take this matter into consideration and to act in an advisory capacity to those hospital governors and trustees who are seeking solution of the problem.

Central Fund for Provincial Hospitals.

At the annual meeting of the British Hospitals' Association in Liverpool last May a resolution was passed approving of the formation of a central fund for provincial hospitals on the lines of the King Edward VII Hospital Fund for London, and asking the council of the Hospitals' Association to take the matter into active consideration. In London there are 112 hospitals which come under the supervision of the King Edward VII Hospital Fund and receive grants and guidance from that body. There are 641 voluntary hospitals in England and Wales and 90 in Scotland, a total of 731, but there is no similar fund in existence for assisting the hospitals in the provinces. Sir Napier Burnett says that, having visited the great majority of the hospitals in the provinces, he has been impressed with the eagerness with which information regarding other hospitals is sought for with the object of benefiting from the experience of others. The hospitals have practically no relations with neighbouring hospitals, and this spirit of isolation reveals itself in the annual reports, which show an almost complete absence of uniformity in keeping accounts or of recording other statistics. The establishment of a clearing house of hospital administration would be one of the main functions of a central fund, and the essential need of such a fund for provincial hospitals is to enable some influence to be brought to bear upon the hospitals, through grants of money, in order to secure a higher standard of administration and a greater degree of uniformity in their statistical returns, and in order to eliminate duplication and overlapping of effort. The Central Fund could have its own technical staff, who would make periodical examinations of each hospital, both as to management and financial arrangements, and on these inspectors' reports the Central Fund would be in a position to allocate grants on a satisfactory basis.

THE MEDICAL DEFENCE UNION.

The annual statutory general meeting of the Medical Defence Union, Ltd., was held at Birmingham, in the offices of the Birmingham Panel Committee, on September 28th. The President, Sir CHARLES A. BALANCE, K.C.M.G., C.B., M.V.O., was in the chair, and upwards of forty other members were present.

In moving the adoption of the report of the Council for the year 1921-22 the President congratulated the members on the satisfactory progress made by the Union during the last three years. The membership was now over 10,000, and the Union could justly claim to be the largest and premier organization of the kind in the country. The number of new members elected in 1921 was 661, but in the current year 979 new members had already been elected—a far greater number than had been elected in any previous year since the Union had been founded. This, he said, was an indication of the extent to which the Union was recognized by the profession as a protection in its hazardous calling, and he paid a warm tribute to the tactful and efficient conduct of the cases dealt with by the general secretary and the solicitor. It was particularly appropriate that the annual meeting should be held in Birmingham, in which city the registered offices of the Union had been located for some six years in its earlier days. In view of the close association of the Union with Birmingham in the past it was, however, to be regretted that the present membership in Birmingham compared unfavourably with that in several other large teaching centres, and he hoped those present would make it their business to rectify the matter without delay. The medical practitioner should not only consider his own selfish interests. He should be prepared to support his brother practitioners and to uphold the prestige of the great profession to which he belongs. No one engaged in medical practice could afford to plough his own furrow or to dispense with the protection afforded by a medical defence organization. The letters received almost daily were testimony to the assistance members obtained in their difficulties from the experienced and efficient action taken by the Union on their behalf. Moreover, as a member of the Union, a practitioner not only protected himself against unjust actions, but was helping to protect others.

The annual report of the council and the financial statement for the year 1921 were adopted unanimously.

The usual statutory resolution was passed and a hearty vote of thanks to the president and council for their services during the past year concluded the proceedings.

British Medical Journal.

SATURDAY, OCTOBER 7TH, 1922.

LETHARGIC ENCEPHALITIS.

FEW epidemic diseases in modern times can have aroused more general interest or provoked so much discussion and research as lethargic or epidemic encephalitis. The student of the literature of this disease may well be dismayed at its immense mass and will welcome the appearance of the report issued by the Ministry of Health, an analysis of which appears at page 654. Some such sifting of the accumulated pile of clinical and pathological material was badly needed, and in taking stock of the results of work extending over nearly four years we may be glad to find how much solid achievement can be recorded. In the first place, it is now generally conceded that the disease is a definite clinical and pathological entity. The pathology rests on a sure foundation of established fact, and although the actual histological changes found in the central nervous system may closely resemble those in other conditions, and notably in acute poliomyelitis, yet there are differences sufficiently distinctive to enable the experienced pathologist to make a definite diagnosis in any given case.

The large amount of experimental work performed in this country, in America, and on the Continent, has been successful in establishing that the cause of the disease is a filterable virus closely analogous to that of acute poliomyelitis. One of the most recent and hopeful achievements of experimental work has been the artificial production of an immunity to the disease in rabbits by vaccination with the living virus. Clinical observations have been equally fruitful in results. Indeed, the number of "types" or varieties of the disease reported has proved confusing. But despite the almost bewildering number of shapes under which the disease may appear there are yet some characteristic clinical pictures. Of these the first and most important is that which Netter originally described as the "triad" of symptoms, consisting of somnolence, fever, and ocular palsies. Next in importance we would place the form in which the clinical picture of paralysis agitans is produced—the so-called Parkinsonian type. In this form the disease constitutes a very striking and characteristic clinical picture which is even now not sufficiently recognized. Nor is it realized how commonly this Parkinsonian state is progressive and terminates in death within a space to be measured by twelve or fifteen months. Another type, sufficiently striking to deserve a name to itself, is the myoclonic form; it may vary from occasional involuntary muscular contractions, enough just to disturb the patient or arouse the interest of the medical practitioner, to a condition where the patient lies in a classical "typhoid state," to which violent and irregular muscular contractions, especially of the abdominal musculature, lend a profound and, to the experienced eye, a disquieting significance.

To the mental changes induced by the disease too little attention has been paid. Even when the patient seems to have made a good recovery it will usually be found that some degree of mental disability remains. On this point especially we are in urgent need of further information. This uncertainty, and the not infrequent cases in which relapses or recrudescences seem to take place, combine to make prognosis a matter of exceptional difficulty. He will probably be wise who takes pains to emphasize the gravity of the disease save in

the most mild cases. Diagnosis also abounds in pitfalls. Except in certain cases—like that of the Parkinsonian type, where the picture is characteristic—it is generally safer to proceed to a diagnosis by way of exclusion than by any other method. The conditions most likely to be confused with it are, according to the report of the Ministry of Health, tuberculous meningitis, cerebral tumour, and cerebral haemorrhage. To this list it would be wise to add syphilis of the nervous system. Obviously therefore, the aid of the pathologist should be sought in the examination of the cerebro-spinal fluid. For although he may not be able to find any absolutely typical changes, especially in late cases, yet a negative report will often be of great value by excluding tuberculous or syphilitic conditions.

We have already touched on the need for care in giving a prognosis. This caution is especially necessary when it is remembered that as yet we have no specific remedy, though we may hope that the experimental workers will perhaps be able to provide us with a truly specific method of treatment. In certain cases of the Parkinsonian type it seems that the administration of hyoscine in full doses has been productive of good, albeit of temporary, results. The treatment by means of fixation abscess, so much advocated in France, has not been much followed here. Nor has the treatment by urotropine or hexamine been much more satisfactory. In fact, we have yet to find a drug which can exert an effect on such inflammations of the central nervous system as encephalitis lethargica or acute poliomyelitis. It is perhaps, not out of place to remind our readers that lethargic encephalitis is now notifiable. The value of such notification is apparent when we have an opportunity of studying such a report as that shortly to be published by the Ministry of Health. For without notification this report would have been impossible. Co-operation between all branches of the profession is always desirable, and never so much as in the investigation of a new disease. Such co-operation has been achieved in the case of encephalitis lethargica with the most happy results.

VINDICATION OF THE VICTORIANS.

SOME of our younger Georgian writers who have been enjoying the pastime of making the Great Victorians run the gauntlet of their criticism have caused Professor Karl Pearson to empty the vials of his wrath upon their heads. The Director of the Biometric and Galton Laboratories is angry with the rising generation, first because it attempts to defame Charles Darwin, the greatest of the Victorians, and secondly, because it fails to appreciate the greatness and goodness of Darwin's cousin—Francis Galton. In a centenary appreciation (Galton was born in 1822) Pearson justifies his attitude in hot and vigorous phrases. "The present generation," writes Professor Pearson, "are apt to speak of the Victorian or mid-Victorian age with contempt . . . They fix their attention on Tennyson's *Idylls*, on suite of furniture sold in the sixties in Tottenham Court Road, or on a product of the old Art Union, and scornfully mutter 'mid-Victorian!' . . . They forget the revolution in thought which the scientists of the so-called Victorian era—Darwin, Lyell, Maxwell, and Kelvin, to confine our attention solely to British names—brought about. . . . Darwin spent ten years collecting data before he allowed his imagination to play upon them and then he revolutionized the whole attitude of men towards the biological sciences. In a certain sense it matters little whether the factors suggested by Darwi

¹ *Questions of the Day and of the Future*, No. xi. Francis Galton 1822-1922. A Centenary Appreciation by Karl Pearson, F.R.S. (20 p. 2s. net.)

as the causes of Evolution have or have not the full weight he placed on them. What does matter is that his ideas revolutionized the methods of research and teaching in anatomy, anthropology, botany, embryology, physiology and zoology. . . . After Darwin the universe can never be the same to the educated mind as it was before Darwin."

There are few readers of this JOURNAL, whether they be Victorians, Georgians, or, as most of us are, a mixture of the two, who will dissent from the verdict which Professor Pearson has passed on the nature of the revolution which was effected by Darwin. Medical men are too familiar with the facts on which Darwin's theory is based to be perturbed by special pleadings in the popular press. Indeed medical men will the more readily understand the present position of Darwinism because they know how Listerism stands. The superficial observer, when he sees that the modern surgeon no longer douches wounds with strong antiseptics or uses the spray, might conclude that Listerism is dead; but the surgeon himself knows that his modern means of dealing with wounds are based on Lister's teaching. It is so with Darwinism; natural selection, the effects of use and disuse, and the influence of environment may not be the potent forces Darwin supposed them to be—but the truth of evolution stands as firmly as when he left it.

Beyond doubt, Professor Pearson is right in placing Darwin's cousin—Sir Francis Galton—among the great Victorians. The two cousins had points in common, and points which make them interesting studies in contrast. Both laid the fruits of their labours in all humility before their contemporaries; neither sought to unload his wares on the public either by threat or cajolery; anyone who desired their wares might help himself and welcome. Darwin was content merely to formulate his pangenetic theory of heredity; Galton put it to the test of experiment and became a Weismannist before Weismannism was born. Darwin ceased his inquiries when he had proved that mankind was the product of evolution; at the point where Darwin left off Galton began. If evolution can raise mankind from apedom and from the jungle to his present estate, how much farther may it not raise him? This was the question which formulated itself in Galton's mind after the publication of the *Origin of Species* in 1859. He spent the remainder of his life in seeking to discover how evolution can be harnessed in the service of humanity—to pull man himself some rungs up the evolutionary ladder. He discovered the principles of eugenics, and offered his discovery to England as a gift. He was convinced that the nation who adopted this child of his would outstrip all its rivals. Even in the nature of his bequest we realize the difference in the minds of Darwin and Galton. Darwin, having published the evidence, left his theory to its fate; he was a pure scientist, believing in the survival of the fittest. Galton, on the other hand, was an "applied scientist," and believed that even the fittest needed protection. Hence he not only left his child "eugenics" to the nation, but also provided a nursery or laboratory for its maintenance, and the fittest tutor in all England to bring this child to the age of maturity—Professor Karl Pearson.

It cannot be said that the British people, not even that part of it which has been trained in medicine, has shown any undue alacrity in taking the Galtonian bequest to heart. Even Professor Pearson, as one gathers from the opening paragraph of his newly issued pamphlet, is not altogether satisfied with the reception that the present generation is extending to things "eugenical." "The year," he writes, "which forms the centenary of Francis Galton's birth demands more recognition of the part he played in the spread of human knowledge and its application to the future of the human race than appears thus far likely to be forthcoming." For he (Professor Pearson) realizes that the time is

hardly suited to impressing on the majority of men a conviction of the futility of most of their aims, of the depth of their ignorance of what makes for progress, and the unsatisfying nature of their present pleasures. No one can say that Professor Pearson seeks for adherents by first intoxicating them with self-satisfaction.

A man who has great talents, who is master of precise methods and a wide knowledge, one, too, who is in deadly earnest, is never the man whom this JOURNAL will treat lightly. We are therefore glad to note in the concluding paragraphs of his pamphlet that Professor Pearson is able to strike the following happier and more hopeful note: "In 1911 Galton died and by his will founded the laboratory which bears his name, a laboratory for the study of national eugenics, for what makes for better breeding in man. It may not be of serious weight, but at least it indicates the tendency of human social evolution when it is reported that during the brief life of that laboratory there has been an increasing number of intelligent inquiries (either directly or, what is more significant, through their medical men) from those about to marry as to the advisability of their proposed marriages, or from those already married as to the morality of their having or not having children." We wish the Galton Laboratory all success, for those who know best the tricks of the little god Cupid will most fully realize the forces which militate against the rationalized matings of human beings, and the obstacles which the Galtonian school has to overcome.

POST-GRADUATE COURSES.

Two recent experiments in arranging post-graduate courses appear to have been so successful as to be worthy of description. A week's course given at Addenbrooke's Hospital, Cambridge, from September 25th to September 30th, was designed to interest general practitioners in the area from which that hospital draws its patients. About 180 notices were sent out, and 60 favourable replies were received. Between 20 and 30 practitioners attended each lecture or demonstration. The difference was accounted for by the fact that those who attended continued to conduct their practices throughout the week, and often lived at a considerable distance from Cambridge, so that each practitioner was only able to attend a few of the lectures. The lectures did not as a rule begin before 11.30 a.m., and the work was finished by 4.30 p.m. The syllabus was drawn up on the basis of a "refresher" course, with illustrations of modern methods of diagnosis and treatment. There were demonstrations by the physicians of some nervous diseases, of diseases of the blood, of cardio-renal cases, and of cases of cardiac irregularities. The surgeons, in addition to operating, gave demonstrations on hip-joint disease and on some surgical aspects of gastric disease. There were demonstrations also of eye, throat and nose, and uterine cases; of the treatment of syphilis and gonorrhoea, and of the simpler methods of the clinical laboratory. Presumably to relieve the monotony of a purely "refresher" course, a short space of time was devoted to bilharziasis in man and to the tubercle bacillus in domestic animals. A week-end course at St. Mary's Hospital, London, also designed for general practitioners, began at 10 a.m. on Saturday, September 30th, and ended at 3.30 p.m. on Monday, October 2nd. On Sunday the work was limited to the morning. Most of the lecturers were restricted to three-quarters of an hour, and arrangements were made for a break in the work, both morning and afternoon, in order that those attending might have opportunity for conversation. Though the announcement of the course had only been sent to a limited number of practitioners, principally old St. Mary's men, the attendance at several of the lectures reached the astonishing total of between fifty and sixty. Some of the practitioners had come from considerable distances in the country, and had thought it worth while to arrange at short notice to spend a week-end in London. The course was

something more than a "refresher" course, and included such subjects as the modern methods of investigating asthma, the clinical application of biochemistry, and the use and abuse of organotherapy. The success of these two courses shows that there exists a demand amongst general practitioners for post-graduate teaching, provided the subjects appeal to them and the arrangements are convenient. The factors in success were probably the time of year, the shortness of the courses, careful selection of the subjects and of the teachers, attention to the comfort of those who attended, and the fact that both courses were free. In all these matters it is clear that the teachers had thought out their plans most carefully, and Dr. Aldren Wright, the secretary at Cambridge, and Dr. C. M. Wilson, the Dean at St. Mary's Hospital, are to be congratulated on the success of their efforts. At the same time it must be said that neither of these successful experiments meets fully the requirements of post-graduate education in England. If this country is to take its proper position in post-graduate teaching it is necessary that facilities should also be provided for practitioners wishing to undertake practical training, particularly in special departments and subjects; that there should be opportunities for training in research; and that in both respects provision should be made for the post-graduate from the Dominions and abroad. Rightly, no doubt, the course at Cambridge was confined to Addenbrooke's Hospital, but there exist in Cambridge teachers and laboratories with every equipment for advanced post-graduate teaching, and it might be possible to arrange suitable courses for suitable students. In London and elsewhere fuller use of special hospitals might be made, and opportunities for research already considerable, could be enlarged. The development of facilities for post-graduate students from abroad is still in its infancy, and needs propaganda, organization, and the provision of social amenities. At the present stage it is probably wise that, where possible, post-graduate courses should be given free of charge, as was the case at Cambridge and St. Mary's Hospital. That a certain demand exists cannot be doubted, and that a much greater demand could be created is probable. It is not too soon to begin thinking out a definite plan for the future. It is possible that on some occasions in the past courses have been arranged which were both too lengthy and too costly. The financial aspect of the matter will require very careful investigation, and must be considered under the separate headings of administrative expenses and the payment of teachers. This discrimination was made by the Fellowship of Medicine when it approached the Ministry of Health last July with the suggestion that the Ministry should give assistance in meeting the costs of administration. The Minister was insistent on the need for the production of a more comprehensive scheme. In this we believe he was right, and it is to be hoped that the Fellowship will take the earliest opportunity to prepare such a scheme. In doing this it may obtain some measure of assistance from the study of the reasons for the success of such ventures as those here described.

"THE GOLD-HEADED CANE."

The well-known *Gold-Headed Cane*, containing a store of interesting medical gossip, mainly of the eighteenth century, appeared anonymously in 1827, and was followed the next year by a second edition expanded by 88 new pages of biography. The author was William Macmichael (1784-1839), Registrar of the Royal College of Physicians of London (1824-29), and author of the *Lives of British Physicians* (1830); he was also a protégé of the Court physician and President of the College, Sir Henry Hallford, disrespectfully described as the "eel-backed baronet" by James Wardrop, M.D., Surgeon to George IV, the witty but sharp-tongued author of "The Intercepted Letters" in the *Lancet* (1834). It is perhaps not a mere coincidence that Sir Henry Hallford's biographer and admirer, the late Dr. William Munk, brought out the third and last edition of the *Gold-Headed Cane* in 1884, with the further addition of

76 pages devoted to Sir Henry Hallford, Dr. J. A. Paris, and Thomas Mayo, the Presidents of the College from 1820 to 1862, and to shorter notices of Sir W. Browne, Pelham Warren, Sir Thomas Millington, Thomas Wharton, John Conolly and others. The original work purported to be the memoirs of a gold-headed cane carried successively by the famous physicians Radcliffe, Mead, Askew, William and David Pitarin, and Matthew Baillie, of whom pleasant accounts were given. The actual cane was presented by Matthew Baillie's widow to the College just before the present building in Pall Mall East was opened on June 25th, 1825, with due ceremony, an eloquent Latin Oration by Sir Henry Hallford, and a banquet attended by five Royal Dukes. As those interested in medical history have become more numerous the *Gold-Headed Cane* has become more difficult to pick up in second-hand book shops; and, as American physicians have shown their appreciation of the work, it was not unnatural that in 1915 a reprint of the second edition was published by Paul B. Hoeber of New York, with an introduction by Sir William Osler and a preface by Dr. Francis Packard of Philadelphia, the present editor of *The Annals of Medical History*. The second, rather than the fuller third, edition was chosen for reprinting because it had been revised, added to, and published by Macmichael, whereas the third edition, although containing most interesting additions, was "not Macmichael's and therefore not the Cane's." This may be perfectly correct, but probably many readers would be willing to sacrifice this rectitude for the further biographical details contained in Munk's edition. The 1915 reprint has now been exactly reproduced, except that the name of the Oxford University Press, London, appears on the title-page in the place of "New York: Paul B. Hoeber, 1915," and that there is a note to the effect that it was printed in the United States of America in December, 1919, from plates made after printing the first edition. It is excellently got up, and will be extremely welcome to those who have not been fortunate enough to secure copies of the earlier editions.

THE ROCKEFELLER INTERNATIONAL HEALTH BOARD.

The eighth annual report of the International Health Board of the Rockefeller Foundation has been issued. During 1921 the policy was maintained of furthering scientific research in order to extend its benefits to the public health without regard to political frontiers. Among the larger duties undertaken by the Board is the co-ordination of measures for the control of yellow fever. This disease, which has worked such havoc among the tropical and semi-tropical regions of North and South America, is a problem too difficult to be solved by any nation acting alone. Despite the most rigid quarantine rules the infection overran national boundaries, desolated populations, and paralysed industry and trade. It was found, for instance, that while Guatemala suppressed an epidemic which had spread to sixteen communities on the Pacific coast in 1918, the infection was reintroduced in the following year. Now, by international co-operation, unified control is being administered over the entire region. In each country active measures are carried out by a Yellow Fever Commission created by special decree under the national department of health, and unity of effort is secured by giving the International Health Board representation on each of these Commissions. During 1921 operations for the control of yellow fever were continued in Peru, Yucatan, Central America, and Brazil. The fight against malaria also was kept going and steadily extended, particularly in the southern states of the United States. To meet the growing demand for doctors and sanitary engineers with special training in this field the International Health Board has undertaken to maintain a considerable reserve corps through a period of apprenticeship; on completion of their training they are taken into federal, state, or

¹ *The Gold-Headed Cane*. By William Macmichael, M.D. With an introduction by Sir William Osler, B.A., M.D., F.R.S., and a preface by Francis R. Packard, M.D. London: Humphrey Milford, Oxford University Press. 1922. (Post 8vo, pp. xxiv+261; 12 figures. 16s. net.)

county service. The commission which the Board sent to France in 1917 to aid in organizing a national crusade against tuberculosis is approaching the end of its task. The general policy is to use the funds and officers of the Rockefeller Foundation to start a campaign, and after this has been set going and its purpose is thoroughly understood by the local authority, to leave its continuance to that authority. When the work in France began the French Government and people were staggering under the burdens of an exhaustive war, and had to bear the added weight of a heavy tuberculosis rate which was thought to be on the increase. A great multiplicity of agencies, French and American, official and non-official, pooled their interests and projected a co-operative scheme on a national scale. Tuberculosis dispensaries were established, medical practitioners received special training, a national campaign of popular education was conducted, and the provision of hospital beds and sanatoriums was stimulated. The activities begun in 1917 are now regarded as rooted in French soil. The Commission has therefore been dissolved, and responsibility is being rapidly transferred to French authorities. Another widespread campaign promoted by the Board is that against ankylostomiasis. This was chosen for special consideration, not primarily because of its importance as a disabling disease, but rather because it furnishes so good an object lesson in methods of control. During the year the Board contributed towards demonstrations in hookworm control in 43 states and countries throughout the world. It completed surveys in Brazil, New Guinea, the Solomon Islands, Tasmania, and Queensland; and began surveys in New South Wales, Western Australia, and the Northern Territory of Australia. Reinfection surveys, to determine the results of previous work, and to stimulate further efforts, have been undertaken in the southern United States, Jamaica, and Brazil. Lastly, the Board intends to go on with its plan of contributing largely from time to time towards the development of a limited number of schools of hygiene at strategic points throughout the world.

FOOD POISONING DUE TO TRIFLE.

DURING the last two or three months some varied types of food-poisoning outbreaks have been encountered. The Loch Maree outbreak of botulism, the first of its kind recorded in these islands, has been referred to in these columns, and there have lately been outbreaks of food poisoning due to Canadian cheese, ascribed to bacterial toxin the nature of which was undiscovered. A few weeks ago an outbreak of food poisoning of another uncommon type occurred. The cause of it, *B. enteritidis* Gaertner, is not the member of the Gaertner group commonly encountered in this country in outbreaks of food poisoning, *B. suispestifer* (*B. aertrycke*), of the "Mutton" type, usually being found. Parenthetically it should be noted that the word "Mutton" is a surname, and the type is not necessarily associated with consumption of mutton, which very rarely gives rise to food poisoning. Early in September a wedding reception was held at Wallasey, attended by some 80 persons. Fully half of those present were attacked, mostly about twenty-four hours later, with severe and persistent colicky pains, severe vomiting, and diarrhoea. It was at first erroneously supposed that foodstuffs had become contaminated with arsenic, as the hall had recently been redecorated internally with green paint. A useful clue to the food incriminated was furnished by the fact that some trifle was given to the caretaker of the hall in which the reception was held, who shared it with several outside persons, who also were attacked with similar symptoms. This hypothesis as to cause was confirmed by investigation of the articles of food consumed by many of the wedding guests, which indicated that trifle was the foodstuff implicated. Of four dishes of trifle prepared for the banquet by a Liverpool catering firm of high standing one remained untouched; from it Professor J. M. Beattie, of Liverpool University, recovered *B. enteritidis* Gaertner; its activity was confirmed by agglutination tests against standard serums and the bloods of several of the

patients; in addition, the same organism was isolated from the faeces of some of the patients. The blood of those who prepared the trifles was investigated, with negative result. Up to the present the way in which the trifles became infected remains undiscovered. It is curious that outbreaks of food poisoning, caused by a Gaertner organism, due to consumption of such articles as cream cakes or trifle, though practically unrecognized in this country, are quite common on the Continent, in France especially. The common factors in such Continental outbreaks, which are usually on a fairly large scale, almost always include some festivity at which articles of food of the nature of cream cakes, trifles, etc., containing whipped cream and white of egg, were consumed. In the Wallasey outbreak the trifle is stated to have contained no egg, custard powder having been used. Whether or not egg albumen was present, such an article as trifle would be a suitable culture medium if contaminated by the specific bacillus. These Continental outbreaks have on numerous occasions in recent years been proved to be due to organisms of the Gaertner group. "Carriers" have, in some outbreaks, been incriminated; in the Cholet (France) outbreak, in 1913, 36 persons were attacked at a wedding banquet, 10 with fatal result. The subsequent researches of Professor Chantemesse showed that the female cook who prepared the "crème royale" for this banquet had already been implicated in four previous food-poisoning outbreaks since 1902. In one instance more than half, and in another 70 out of 100, of the wedding guests were attacked; in another instance 25 persons were affected; and at another wedding banquet a number of guests suffered from a similar kind of illness. After the Cholet outbreak this cook was found to be a Gaertner "carrier." There are, however, outbreaks of this kind where no evidence of a "carrier" can be obtained, and in them, where eggs have been used, it is possible that specific infection may have been derived from the egg itself. It is known that Gaertner organisms may cause disease in birds. Sparrows and canaries may suffer from enteritis due to a Gaertner organism. In 1892 *B. psittacosis*, which is probably identical with *B. suispestifer* (*B. aertrycke*), caused in Paris an outbreak in parrots which spread to man, 42 persons being affected, of whom 14 died. Attention may be drawn also to an article by Lignières and Zábala, who had observed in Argentina many outbreaks in fowls of a disease to which they gave the name "salmonellose aviaire," as its cause is a bacillus of the Gaertner group (the salmonellae). As outbreaks of this kind are associated with consumption of cream cakes and trifles, usually containing white of egg, it is not unreasonable to suppose, in the absence in any outbreak of evidence of a Gaertner "carrier," or other source of infection, that the Gaertner organism may at times be present in an infected egg, by means of which a foodstuff furnishing a suitable culture medium may become infected.

INDUSTRIAL HYGIENE.

It was announced recently in our columns (May 13th, p. 776) that the Industrial Hygiene Section of the International Labour Office of the League of Nations intended to publish bibliographical notes on industrial hygiene in the *International Labour Review*. The first of these bibliographies was issued with the May number of the *Review*. If they are continued on the same scale they should prove of great utility to everyone interested in industrial hygiene and allied subjects. Many of the papers and articles recorded were published in foreign periodicals which the average reader is not likely to consult unless his attention is specially called to them. To some of them, unfortunately, he would find it very difficult to obtain access in this country, but the fact that references are given to periodicals not at present subscribed for by British libraries will no doubt stimulate some of them to subscribe in the future. The literature is tabulated under several main headings, such as "Hygiene and Health in Trades and Occupations," "Hygiene and Health of the Worker," and "Industrial

Physiology and Pathology," and each of those is split into smaller sections. Altogether 173 notices are tabulated in the May and June numbers of the *Review*, the largest number relating to the third of the headings mentioned. More interesting to the general reader than a mere bibliography is the series of articles and reviews on problems of industrial hygiene, which are published every month in the *Review*. In the June number, for instance, there is a lengthy summary of the Second Annual Report of the Industrial Fatigue Research Board, and other reviews. Special attention is paid to the subject of vocational guidance, and we learn that institutes dealing with this problem have been started in Spain, Switzerland, Germany, and other countries, with Government assistance. In Czechoslovakia the Central Bureau has organized a number of propaganda conferences, and collected data from workers and manufacturers relating to various occupations; many personal visits also were paid by the Council of Management to the workshops. A vocational guidance office has been set up, where the adviser talks over the chosen occupation with the child and his parents, and extracts information about the child's tastes and character. After a free medical examination and psychological test at the Labour Academy, the adviser is in a position to approve the child's choice or to suggest an alternative. In our own country the state of public opinion has not advanced so rapidly as it might, and vocational guidance has not yet received the official support it deserves. Fortunately, an unofficial undertaking, the National Institute of Industrial Psychology, has been founded by the co-operation of a number of employers and psychologists interested in the subject, and the work already done by the institute, as described in its *Journal*, is full of encouragement for the future. A summary of the work and aims of the institute is given in the *Review*.

THE SPA PHYSICIAN IN FRANCE.

PROBABLY many members of the profession who suffer from bronchitis or other conditions aggravated by the English winter climate have thought it would be agreeable to practise in a watering place in the south of France, for many of these are admirably situated in regions of lake and mountain or on the shores of the Mediterranean. The difficulty, however, of obtaining authorization to practise in France is virtually insurmountable; it is necessary to hold a French university diploma conferring the right to practise, and it is to be noted that not all degrees granted by universities in France confer this right. A correspondent who had not to encounter this difficulty, since in his youth, by a stroke of luck, he had taken a degree at the time when protection was not so strict, had only to register his diploma at the prefecture of the department in which he wished to practise; nevertheless, it was not quite plain sailing even for him. Like others, he intended to choose a place frequented by English and Americans, feeling justified in assuming that an Englishman or Englishwoman would prefer an English medical adviser if one were available. With Americans, he says, the attraction of an English-speaking doctor does not seem to be very strong, for if they do not find one of their own nationality they often seem to prefer to consult a French doctor. Our correspondent goes on to relate some of his early troubles. "The place I selected after carefully pondering over the matter was," he says, "renowned for its hot springs and the very elaborate methods of applying these waters for the relief of human suffering. I had letters of introduction to sundry of my future colleagues, but as soon as I announced my intention of settling down among them, though still polite and even cordial, they persistently evaded my questions as to the uses of the waters and the methods of treatment in vogue. Of course I diligently read up all that had been published and advertised about the place, and a time came when I began to see as through a glass darkly. Then, too, I made the acquaintance of the dean of the local faculty—that is to say, the oldest among them, and also the most large-hearted, for he happened to be a man who ought to have been a professor in a teaching centre; in other words,

he derived pleasure from imparting knowledge. In pleasing contrast to his colleagues, he displayed the greatest readiness to initiate me into the mysteries of the balneological art, so that theoretically, at any rate, I soon acquired a sound foundation. But, as every practitioner of experience is aware, there are special qualities that make for success in practice quite independent of mere technical knowledge, and this is particularly the case in spa practice, where patients are not imbued with the confidence that comes of years of acquaintanceship. The patient knows nothing of you except that you have been recommended to him by his doctor in Paris or London, and he preserves an open mind. You have to find out how much attention the individual patient requires or desires—for the two are not synonymous; some patients can assimilate a lot of professional advice, others are less tolerant, and would dispense with it altogether if they only know how. If written instructions for the baths are given, some patients pass them on to their friends, irrespective of their condition, or themselves use them in the following year, without reflecting that the condition of their health may have changed. There are a thousand and one little, but not insignificant, details to master in connexion with the *Établissement des Bains*; for instance, to secure punctuality of the porters and the proper execution of one's prescription by the *doucheurs* are not always easy matters, inasmuch as they have ideas of their own on the subject. It is necessary also to see that the patient is provided with the proper garments and takes an adequate rest after the baths, and so on. Such knowledge can only be gained in actual practice. Once it has been acquired it is seen to be simple enough. There are not fifty ways of taking a bath or a *douche*, and *massago* cannot be modified *ad infinitum*."

HEALTH OF EUROPEAN OFFICIALS IN WEST AFRICA.

IN the annual report for 1921 on the vital statistics of non-native officials in West Africa, issued recently by the Crown Agents for the Colonies, it is stated that not only has there been a considerable improvement in the death and invaliding rates as compared with those for 1920, but that the former is almost the same and the latter less than the similar rates for the last complete pre-war year, 1913. The death rate reached the third lowest figure on record, being surpassed only by the years 1913 and 1916, while the invaliding rate was the second lowest on record, the year 1917 alone being lower. The reversion to normal conditions in West Africa was generally complete in the year under review, and comparison may once more fairly be made with the records of the pre-war years. The death rate has fallen from 16.3 per 1,000 in 1920 to 12 per 1,000 in 1921, a decrease of 4.3 per 1,000. This improvement is due to a great extent to the excellent figures for Nigeria, where the death rate is only 8.4 per 1,000, as against a rate of 20 per 1,000 for the Gold Coast. Thirty-seven deaths took place during the year; the chief causes of death were blackwater fever (7 cases), malaria, pneumonia, and heart disease. The invaliding rate is 16.6 per 1,000; this rate has shown practically a continuous improvement ever since the statistics were first compiled, and is now only a quarter of that recorded seventeen years ago. The number of non-native officials in the service on January 1st, 1921, was 2,875, 48 being in Gambia, 228 in Sierra Leone, 852 in the Gold Coast, and 1,747 in Nigeria.

CARNEGIE AWARD TO A MEDICAL MAN.

THE Carnegie Hero Fund trustees have awarded a medallion and an annuity of £130 to Dr. John Spence of Edinburgh, in recognition of his valuable and heroic work in radiology. Dr. Spence was among the first in Scotland to take up research in x-rays and medical electricity, and as a result of radiological experiments he sustained serious damage to both hands, necessitating amputation of the right forearm. Dr. Spence is still carrying on his work as radiologist at Leith Hospital and Craigleith Hospital, Edinburgh.

ENCEPHALITIS LETHARGICA.

MINISTRY OF HEALTH REPORT.

THE Ministry of Health is shortly issuing as one of its Reports on Public Health and Medical Subjects a report on encephalitis lethargica, a copy of which we have been privileged to see. Amongst the enormous mass of literature on the subject this report should be destined to take a high place. It is a work wherein the neurologist, the general practitioner, and the medical officer of health may all find a profitable study.

Sir George Nowman in his introduction explains the scope of the inquiry and summarizes the most important conclusions reached. We may be allowed to concur entirely with his statement that "it is probable that this report will prove of greatest value as a storehouse of statistical information, and in the large number of pages devoted to the appendices is safely garnered a wealth of facts and figures such as I do not think have been collected in any other similar report."

Dr. Allan Parsons is responsible for the greater part of the report itself, and he has dealt in a lucid and comprehensive manner with the immense mass of material at his disposal. After a brief introduction to the disease as it first appeared in this country he describes the method of inquiry which was pursued, and we are able to deduce the amount of painstaking study involved. The epidemiology and etiology are next considered, many statistical charts and tables being incorporated, which add very much to the value of the text. The possible relationships of influenza and poliomyelitis to encephalitis lethargica are fully discussed, as well as the interesting condition of "epidemic hiccough," of which some particularly valuable clinical and epidemiological details are given. The important practical questions of infection and contagion are well considered, as well as the problem of the possible carrier. The general opinion regarding the low infectivity of the disease as a whole emerges confirmed from the statistical inquiries on this aspect of the disease. One interesting and probably little known event which is noticed is the transmission of the disease from the mother to the newly born child.

The description of the clinical varieties of the disease is excellent and abounds in descriptive details. An anatomical classification of types is adopted, following the previous work of MacNalty, though the author gratefully mentions the work of Walsh in the classification of the purely nervous symptoms into positive and negative symptoms. Each of the various symptoms is considered in detail, both in what is called the "prodromal period" and in the "declared disease," albeit such an arbitrary division into distinct stages is hardly to be maintained. Tables of the frequency of the different symptoms are given, and altogether this section of the report is full of very valuable information. We think that the importance and frequency of the so-called Parkinsonian syndrome have been scarcely emphasized enough, while the reported frequency of facial, and especially double facial, paralysis leads to the doubt whether this symptom has not been erroneously interpreted as such, it being in reality often but an expression of the rigidity of the facial muscles in these Parkinsonian cases.

The course, complications, and mortality next receive consideration. Most observers will agree with the remark that "the case mortality rate of 48.3 per cent. as derived from the notification figures for 1919 and 1920 must certainly not be taken as a true estimate of the proportion of deaths that occur among people attacked by encephalitis lethargica." For there is no doubt that at this period many slight cases escaped recognition.

We are glad to see that the highly important question of the sequelae is considered and that some details in this respect are given in a very large number of cases in one of the appendices. In the matter of diagnosis it is shown that the conditions in which confusion is most likely to arise are tuberculous meningitis, cerebral tumours, and cerebral haemorrhage; to these it would be well to add syphilitic disease of the nervous system. The importance of the examination of the cerebro-spinal fluid is insisted upon, and this method of examination receives further consideration in a later section. The author wisely advises caution in prognosis, and we are here entirely in agreement with him, especially in regard to the eventually complete recovery or otherwise. The only branch of the symptomatology to which

we would wish that more attention had been devoted is the mental changes which not infrequently occur, and in respect of which much more information is needed.

Dr. MacNalty contributes the section on the pathological anatomy and the experimental work on the transmission of the disease to animals. The morbid anatomy as studied by many different observers is carefully summarized. According to Mackintosh the lesion is definitely inflammatory, and the changes consist of a cellular infiltration of the perivascular lymphatic sheaths and of certain areas of grey matter. Changes in the meninges are slight. In the brain the changes are most conspicuous in the pons and in the basal nuclei. Compared with acute poliomyelitis the amount of neuronophagia is small. The occurrence of the "minute bodies" described by Da Fano and Ingleby is mentioned and their significance discussed.

On the bacteriological side opinion is now unanimous in favour of the view that the virus is a filtrable one. The work of previous observers is described, and this is followed by a full description of the interesting experimental work of Mackintosh arising from the outbreak of encephalitis at Derby in 1919. This observer was the first to be successful in transmitting the disease to animals. A useful table of the points of distinction on pathological grounds between encephalitis lethargica and acute poliomyelitis is given. The conclusion is reached that on pathological grounds the separate identity of encephalitis lethargica is amply proven. A summary of the more recent experimental work of Levaditi, Harvier, and Nicolau is given. These authors have emphasized the presence of healthy carriers of the disease, and have further found that the virus of herpes zoster is of the same nature as that of encephalitis.

The changes in the cerebro-spinal fluid are the subject of a separate report by Dr. Perdrau. This chapter will interest the clinician as well as the pathologist, for the former is often dependent on the report of the findings in the cerebro-spinal fluid to confirm or rebut his clinical diagnosis. Dr. Perdrau concludes that during the acute stages of the disease the following are the chief points to be noticed in the examination of the fluid: (1) a pleocytosis which varies in direct ratio with the severity of the disease; (2) a small increase in the total protein content, the latter not keeping pace with the former (dissociation cyto-albuminique); (3) the cells present are lymphocytes. In the subacute or chronic stage the fluid is practically normal.

Another useful table of comparison is here given, contrasting the changes in the cerebro-spinal fluid in tuberculous meningitis and encephalitis lethargica. A report of further recent experimental work follows, out of which one of the most important results which emerges is the production of an artificial immunity in rabbits by vaccination with the living virus.

We have here attempted only to summarize very briefly the highly interesting contents of this valuable report, but some further comment is made elsewhere in a leading article (p. 649). In conclusion, a special word of praise must be given to the appendices, where may be found a wealth of statistical detail, which will repay careful study. We hardly remember to have seen anywhere a bibliography so complete or so better presented. The index maintains the high standard of the rest of the work. We hope that this short account of a very lengthy report will stimulate readers to investigate it more thoroughly for themselves. The medical profession in this country is under a debt of gratitude to the Ministry of Health for the production of a report which is indeed a worthy monument to the labours of all concerned.

THE MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE SOCIETY.

THE annual general meeting of the Medical Sickness, Annuity, and Life Assurance Society was held at the offices of the company, 300, High Holborn, on October 2nd, when Dr. F. J. ALLAN was in the chair.

Chairman's Address.

Dr. ALLAN said that the report sent out last year was for a period of thirteen months, while that before the meeting was for twelve months, so that there might be a little difficulty in comparing the figures. In both the sickness and the life assurance branches business had been well maintained. The report of the Registrar-General showed that the year 1921 was characterized by a remarkably low death rate,

and that was reflected in the claims for sickness; which were considerably below expectation. There had been rather a large number of accidents from motors, some of them due to starting. In the life insurance section a sound business was steadily being built up. It was necessarily slow work, as it took time for the profession to know that the company was open to transact life assurances up to any amount at particularly low premiums. A number of their members had taken out additional policies with the company, but many medical men were precluded from taking out further life assurances as they were already insured up to their limit. He, however, looked forward to increased business from those who were not insured, and from the younger members of the profession. A branch of insurance which seemed to him to appeal to medical men was the partnership insurance; at the death of a partner the surviving practitioner might be called upon to pay for the share of a practice, and it would be a distinct asset to have an insurance to meet such a claim. One of the advantages the Society offered was that while the premiums were practically equal to the non-profit rates of other companies they were able to recommend the distribution of a bonus. The Society's rates were, he understood, regarded in the insurance world as a notable achievement. They were able to quote low rates because the company was run on mutual principles with no shareholders, no commissions to agents, and strict economy in management. The number of annuitants showed a slight increase; the amount paid to them during the year was £5,000. Those members who in the past paid small premiums to ensure an income on attaining the age of 65 had made a good investment. As an example he quoted one member who had died recently at the age of 87; he had paid in less than £300 and had received a pension of £50 a year for twenty-two years. The management expenses showed an increase, but when discussing the conversion of the Society into a limited company he had explained that the expenses would be greater, especially in the first few years when the company was establishing itself on its new basis, inasmuch as it had to pay directors' fees, etc.; in addition it had been handicapped by increased prices. The directors were, however, satisfied that the expenditure incurred was not excessive. The management expenses on the Sickness and Accident Fund amounted to 15.8 per cent. of the premium income; on the Life Insurance Fund, which included annuities, it was only 8.1 per cent. A standing Finance Committee had been appointed, which had made a close examination of the accounts for a number of years. He looked with confidence to increased prosperity in the Society's work. He moved that the directors' report and the audited balance sheet be received. The motion was carried.

Valuation Report.

The election of three directors and the appointment of auditors for the ensuing year having been duly carried, the CHAIRMAN presented the valuation report prepared by the actuary, Mr. S. G. Warner, F.I.A. The surplus in the life department was not large, as Mr. Warner had valued the net premiums only on what were really non-profit rates. It was therefore, he considered, satisfactory to be in a position to recommend a bonus on the various classes of policies. In the sickness department a substantial surplus of £39,641 was shown, and the directors agreed with the actuary that a proportion of that sum should be returned to the insured. They thought the fairest way would be to give a rebate or reduction of the premiums falling due after the date of that meeting, such rebate being in proportion to the number of years of insurance. Any member who preferred to do so could allow the sum due to him to remain in the hands of the Society to be paid to the member on the termination of the period for which he was insured against sickness and accident. Some disappointment had been felt by members who attained the age of 65 after January 1st, 1919, because on the advice of the actuary no bonus was paid to them on their retirement. Dr. Allan then expressed the hope that, if it was found permissible to issue a bonus at the present valuation, it would be made retrospective. The directors therefore recommended that to those members who attained the age of 65 since January 1st, 1919, and whose insurances had consequently terminated, a cash bonus be paid equal to the full annual premium payable for such insurance during the year prior to its termination. They also recommended that from the surplus in the Sickness Fund £2,000 should be placed to the Staff Pension Fund. The chairman concluded his address by moving that the actuary's report and the recommendations of the directors be received. This was duly carried.

Mr. P. S. CAMPBELL, speaking as a former member of the Committee of Management prior to the Society being converted into a company, said that the members and the directors ought to be congratulated on the excellent position of the

company. He considered that the amount of remuneration paid to the directors was insufficient, and moved that it be increased to three guineas a meeting to each director present; and four guineas for the chairman. The motion, having been duly seconded, was adopted. On the motion of Dr. VINNAGE, seconded by Sir WILLIAM WILCOX, a vote of condolence was directed to be sent to Mrs. Brindley-James on the death of her husband. Dr. KNOWSLEY SIBLEY moved a vote of thanks to the chairman for the enormous amount of work he did for the Society, and this was carried unanimously.

OPENING OF THE WINTER SESSION.

MEDICAL EDUCATION, PAST AND PRESENT.

SIR CLIFFORD ALBUTT'S INAUGURAL ADDRESS AT
ST. GEORGE'S.

THE inaugural address at St. George's Hospital Medical School was delivered on October 2nd by Sir Clifford Albutt.

Sir Clifford Albutt spoke first of his joy on returning to his old school. He was determined to come, even if this service, as a cynic remarked, took the repulsive form of a duty. He detected in himself one note of ego—a disposition to recall the past, if not to dwell upon it. He remembered his own early appearance in the school, a well-intentioned but crude and rudimentary youth. In those days life was far too easy, and competition not keen. In medicine university men were few, and if fairly efficient a consulting practice fell to them without any great exertions in research or specialized study. The men who came to St. George's from Oxford and Cambridge were not supposed to compete with ordinary students for resident posts, nor even for prizes, but clinical clerkships were not grudged them. He served as clinical clerk under two physicians, one of whom, Fuller, he described as gentle fertilizing rain, and the other, Bence Jones, as sheet lightning. From Fuller he learnt much in an empirical fashion. He remembered how, after a thorough examination of the patient, Fuller would draw out a handsome gold pen, dip it cautiously in the ink, and write in a fine hand an imposing prescription for a mixture, as well as directions for a universal pill, for dieting, and for alcohol. Every patient at St. George's at that time had a cohort—some had braids, others who were convalescent had aloe, but there was nothing so vulgar as whisky. Fuller was not a genius, but a kindly, competent, and diligent man. Bence Jones was a fascinating and brilliant personality. He was invariably unpoetical, and the speaker recalled him now, coming up the stairs two or three at a time, with the morning guineas, it was said, scattering out of his pockets as he flew. He would ask which were the worst patients, snatch the poor notes of his clerk, make a rapid diagnosis, and as rapidly scratch in some prescription. Extravagant and whimsical as was this man, it was a sharp and inspiring discipline to be associated with him. Of the surgeons at that time Sir Clifford Albutt could say nothing. He hardly ever entered the surgical ward. This curious division between medicine and surgery was a cramping convention handed down from the Middle Ages and a blight upon the profession for centuries until now. Sir Robert Jones had urged lately the need for a closer integration of medicine and surgery, and Sir Clifford believed that the old division must cease.

At the time to which his memories went back medicine was being reinforced and transformed by the vast developments of natural science. But before every revolution, beneficent as it might be, there must be some destruction of old concepts, the ground must be cleared of antiquated systems and forms, and they had to resign themselves to some permanent or at any rate long-persisting loss. The wistful retrospect of those who, nevertheless, were hoping for and working at the new order was not mere sentiment; and it might well be hoped that, as time went on, changes would not be so cataclysmic as in the past, so that they could better be foreseen and provided for. The conservators must be more sagacious, the reformers more patient. In therapeutics, for example, pharmacologists had done much to clear out of the way antiquated methods and remedies, and purify those which remained. Many combinations of remedies established on theories accepted for generations had slipped out of sight, and, it might be, were altogether forgotten. The harvest was multiplied a thousandfold, yet in the ingathering not a little was lost.

Professional Training.

The speaker then turned to the subject of the education of the student and repeated some of the remarks he had made in his article in the Educational Number of the *BRITISH MEDICAL JOURNAL*.² In professional education he laid stress upon the need for the interpenetration, interweaving, and mutual reinforcement of the sciences on which the art of medicine was founded. As Roger Bacon said nine centuries ago, all the sciences were bound up together and helped each other. The details of the various ancillary sciences they could not be expected to master, still less to remember, but of the main principles they must not be ignorant. They must ever bear in mind that a common cause might run through many groups of various phenomena. It might be that in course of time physiological problems would be capable of explanation and expression in terms of physics and chemistry. They must learn to regard diseases no longer as entities but as phases of biology. They must not think of their education in these sciences as a series of stages, each to be left behind as another was pursued, but rather as the ascent of a mountain, each part of the ascent contributing to the widening view. The teachers at that school would endeavour to lead the students farther along the lines of research. Could any subject seem on first acquaintance less profitable, yet how mighty had been the achievements! Even the Panama Canal depended upon the curiosity of Maudslow and Ross with regard to the guts of the mosquito. He counselled those who were studying medicine to undertake their reading alongside their practice, to study the clinical manuals as far as possible by the bedside, to select the appropriate chapters as chance patients came before them, and compare the clinical notes with the classic descriptions, always remembering, as Bateson said, to "cherish your exceptions." It was often said that in modern medicine instrumental diagnosis was supplanting the direct aid of the senses. While in some respects the eyes and the finger-tips might lose their cunning, he believed that on the whole the instruments stimulated and reinforced an acute observation. In practice, especially in general practice, they had often to go beyond their evidence. The practitioner, having gained a half intuitive insight and foresight, worked on what were called moral certainties, or, to express it differently, on commonsense. Without commonsense in practice they would lose their way again and again. Yet in science commonsense was a treacherous ally, and often in the long run failed them because it allowed to creep in an accumulation of small errors.

Psycho-analysis.

This led him to make some remarks on psychology, which would be better known as the physiology of the mind. The reiteration of the word "psychology" was getting wearisome. People spoke of the psychology of the crowd when they meant simply its temper. It almost seemed as though some writers on the subject really supposed that disorders of the mind were represented by no physical deviations within the substance of the brain. Popular psycho-analysis was false science; it had no units, no means of measurement, no controls, no precise definitions, no separation of objective and subjective evidence. He was doubtful altogether of its virtue. Even pickpockets now were appealing to their judges to regard their cases from the psychological point of view. The method of science was to work on lower categories, and not to explain anything in terms of higher categories before the lower were explored. Psycho-analysis had been known for centuries in the Church as confession and casuistry, and the Roman Church had been well aware of its dangers. Yet, all this experience notwithstanding, it was now proposed that any teacher should be allowed to probe into the minds of adolescents and children, too often with dirty tools. It was false to argue that the soul need not be tainted with foul suggestions. To talk about such things as should not be known or named was to create familiarities which bred temptations. Suggestion did not consist in occasional jabs at the mind, but the mind was open incessantly to suggestion as the lungs to air. Was it unfair to say that the interpretations given by psycho-analysts to the dreams of our modern Jacob and Daniels were incredible nonsense, worse than unsubstantial or extravagant? What was formulated as the subconscious could not contain more than the record of past—and, so far, inferior—experience. It was not possible to get out of a pit pot more than was put in.

The Rewards of the Doctor.

In conclusion, Sir Clifford Allbutt said that every profession had its hardships and its rewards, its rough places and its smooth, its joys and its drudgeries. But in medicine the trials and the blessings came close together. In all honest work there was ultimate good, but in medicine the harvest was gathered on the field almost at the sowing. The task of relieving suffering and restoring health afforded deep satisfactions, even if the patient was not always grateful; and such gratitude usually came eventually, though it might take other forms of expression than the obvious. Those engaged in medicine, in their contact with their patients, did well to cultivate a hopeful outlook. A successful physician once told him that he never left a house without giving a favourable prognosis. It was a counsel which had a colour of world wisdom; but he was right in this, that no one could foresee what benediction words of hope might bestow.

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN.

The new session at the London School of Medicine for Women was opened on the afternoon of October 2nd, when a large company of old and new students met under the chairmanship of the Dean, Miss Louisa Aldrich-Blake, M.D., M.S., who extended a welcome to the fifty entrants and gave an account of the past year's work.

The introductory address was delivered by Viscount Burnham, who spoke of the progress made in the medical education of women during the forty-eight years since the school first opened, and during the forty-five years since its students began to study clinical medicine at the Royal Free Hospital. He reminded his hearers that they inherited the rights and privileges won for them by the efforts of the small band of great women who did pioneer work half a century ago. The inspired courage of women like Elizabeth Blackwell, Sophia Jex-Blake, and Elizabeth Garrett Anderson must never be forgotten. He recalled, in particular, the wonderful achievement of Dr. Garrett Anderson, whose son was to-day their honorary treasurer. The preventive movement in public health was in its infancy during the early days of her struggle for the recognition of women in the medical profession. In the great work of public hygiene women who were fully qualified ought to be employed more and more as their obvious appropriateness to many of its special subjects became clearer and more widely understood. He did not suggest that the branches of medical service should be separated into watertight compartments, but he felt that in the direction of the public health service women had an invitation and an inducement which was perhaps not so clear in all branches. Again, the more the scientific side of the medical profession was extended and developed the more favourable were the opportunities for women's work. This opened up a vista of employment and usefulness outside the ordinary range of medical practice, which, so far as his inquiries had gone, was for the present somewhat limited in the case of women to certain localities. He believed that so far the practice of women doctors had been almost entirely among women. In the future rearrangement of hospital work and the redistribution of organized help to the sick poor it seemed to him that women doctors would find a new occupation specially suited to their special gifts and faculties. In conclusion, Lord Burnham remarked that the new students were entering their profession at a critical time in its history. Efficiency, like co-ordination, had been ridiculed by the scoffers, but for all that they had to be efficient. The world would not accept them as efficient merely because they were women; neither men nor women would be accepted in future on their own valuation. Above all other qualities medical students needed the genius for taking pains and the ideal of human service. To them nothing should be common or unclean except slipshod methods, inaccurate observation, and dishonest pretence of understanding what they did not understand.

Dr. Mary Scharlieb, as President of the School, proposed a vote of thanks to Lord Burnham for his address. Thinking very seriously of the school the other day, she said, it had come to her more clearly than ever before that they were perhaps not pulling quite their own weight in the medical boat. Looking back over the last thirty-five years, it seemed to her that they had done very well as school students; but academic distinctions, though very nice, were after all but the shining pebbles and pretty shells. Of real importance

² The Training of the Medical Student, September 2nd, 1922, p. 407.

was what they were going to be after graduation. Was it not time, she asked, that one of their alumni wrote some epoch-making book or made some important discovery in the field of research? More important than all, ought they not to be foremost in the endeavour to lessen infantile mortality?

ST. BARTHOLOMEW'S HOSPITAL.

The annual Old Students' Dinner of St. Bartholomew's Hospital was held on October 2nd in the Edward VII Rooms, Hotel Victoria, with Sir Charles O'Brien Harding, J.P., M.R.C.S., of Eastbourne, in the chair. There was a large attendance. After the loyal toast had been honoured, the chairman, in proposing prosperity to St. Bartholomew's Hospital, observed that wherever one looked Bart's men were still leading the field; thus the presidents of the two Royal Colleges, the Regius Professor of Medicine at Oxford, and the Vice-Chancellor of the University of London were old students of St. Bartholomew's. The toast was responded to by Lord Stanmore, the new Treasurer, who spoke of the arrangements for the celebration next year of the octocentenary of the hospital and the efforts made to overcome financial difficulties. Sir William Lawrence, Bt., the Senior Almoner, in submitting the toast of "The Medical College," declared that medical education was the paramount function of the hospital. Mr. H. J. Waring, Vice-President of the College and Vice-Chancellor of the University of London, responded, and gave a brief outline of the year's doings. The number of students was now 750—probably the largest on record—and this had emphasized the need for an obstetrical teaching unit and for the new department of physiology. The question of admitting women students had been considered, but it was found impossible to make room for them. Remarkable that the improvement of the hospital buildings had now gone as far as it could, Mr. Waring professed himself, like Sir William Lawrence, an antisentimentalist when it came to a question of preserving old stones or meeting new needs. The health of the visitors was proposed by Sir Thomas Horder, who classified them into "intimate strangers" and academic guests, and so managed to pay several amusing compliments. The Rev. E. C. Pearce, D.D., Vice-Chancellor of the University of Cambridge, and Sir William Thorburn, K.B.E., Emeritus Professor of Clinical Surgery in the University of Manchester, responded. Dr. Pearce said he had had a friendly feeling for St. Bartholomew's ever since as a Christ's Hospital boy (when the two institutions were next-door neighbours) he studied elementary chemistry under Russell, and now as Vice-Chancellor he was pleased to hear how many Bart's students still came from Cambridge. Sir William Thorburn expressed his admiration for the hold of St. Bartholomew's upon medical thought in this country and for its great services to the profession. The Chairman's health was proposed by Sir Anthony Bowlby, President of the Royal College of Surgeons, who said that the good name of Bart's depended on a well-guided and well-served hospital, on a finely equipped medical school, and on the zeal of its workers; but above all on the *esprit de corps* of its old students throughout the world. Their chairman that evening, Sir Charles Harding, was a representative general practitioner in whose hands the reputation of the hospital was safe.

CHARING CROSS HOSPITAL.

The presentation of the prizes at Charing Cross Hospital Medical School took place on the afternoon of October 3rd. In submitting his annual report for the academic year 1921-22 the Dean, Dr. W. J. Fenton, said that the position attained by the school during the war with regard to the number of students entering and the general progress which it showed had been fully maintained, and there was evidence of solid advance. The tendency to an increase in women medical students as compared with men noted in his last report had become less observable. During the last three or four years the entry of medical students had risen to a very high level, and, though it was early to draw conclusions, it seemed probable that a return to a more normal entry, both of men and women, was beginning to show itself. The question had been asked whether the school would continue to admit women students to its curriculum. The answer was that it would continue to do so. The principle of co-education was deliberately adopted some years ago after full discussion, and nothing had occurred in the interval to occasion regret that that course was taken or to require its modification. A glance at the prize list revealed the fact that the greater number of class prizes had been taken by women

students. This should not be regarded as evidence of superiority or otherwise of one sex as compared with the other, but merely one of those periodical fluctuations which adjusted themselves to an average over a series of years. After referring to staff changes during the year Dr. Fenton thanked the teaching staff of the hospital and school for the work they had done and their untiring efforts on behalf of the students. He also thanked the Principal and the Professors of King's College, University of London, for their care and attention on behalf of Charing Cross students. The pass lists, were an eloquent testimony to their good work. The association of the school with King's College in the earlier subjects of the medical curriculum had been most cordial, and after eleven years of concentration on the College for preliminary work he had to record nothing but success.

Viscount Burnham, having presented the prizes, congratulated the renowned school of Charing Cross Hospital on the successful report presented by the Dean and expressed his best wishes to the successful students. He considered them very fortunate to have an opportunity of studying in such a place and under such a staff. He recalled the great interest which his family had always taken in the welfare of Charing Cross Hospital. On the motion of Sir Herbert Waterhouse, seconded by Mr. Peter Daniel, a hearty vote of thanks was accorded to Lord Burnham.

The annual dinner of past and present students was held in the evening at the Imperial Restaurant, with Viscount Burnham in the chair. The toast of "The Hospital and Medical School" was given by Sir Herbert Waterhouse, who referred to the loss the school and hospital had sustained by the retirement of Mr. Stephen Fenwick. He mentioned that Mr. George Verity, chairman of the hospital, had become chairman of the medical school, and that the freehold of the school buildings had been purchased. The toast of "The Students; Past and Present," was given by Dr. W. C. Bosanquet and acknowledged by Dr. Scott for the old students and Mr. Clifford-Smith for the present students. The toast of "The Guests," given by Dr. David Forsyth in a humorous speech, was acknowledged by the Principal of King's College and Dr. Ingleby Oddie, coroner for Westminster. Mr. George Verity, in proposing a vote of thanks to the chairman, said that he hoped the project for a maternity ward would shortly be realized. Viscount Burnham, in his reply, spoke of the interest which through contiguity Fleet Street took in Charing Cross Hospital.

ST. MARY'S HOSPITAL.

The annual dinner of St. Mary's Hospital Medical School took place on October 2nd, when Sir Leonard Rogers, M.D., F.R.S., presided over a company of 140 past and present students. The chairman gave some reminiscences of his student days at the hospital; on one occasion he was a member of a raiding party, which in the dead of night obliterated the sign of an undertaker who advertised cheap funerals under the hospital windows. The speaker referred regretfully to the deaths of Professor Waller, Dr. Mitchell Bird (who had left about £10,000 to the hospital), and the librarian, Mr. Nanfan. Happy was the country, which had no history, also the institution which did its work so quietly and effectively that there was very little to be said about it. Mr. A. R. Prideaux, Chairman of the Hospital Board, mentioned that recently a man who had been brought into the hospital badly injured in a street accident, so that his leg had to be amputated, was so grateful for what was done for him that on his discharge he organized a boxing tournament, which brought in £2,000 for the hospital; moreover, he promised to make it an annual event. Dr. C. M. Wilson, the dean of the school, gave an account of the school's income, which came, he said, from two sources—student fees and State contributions. To justify the continuance of the latter it was necessary to provide something distinctive at St. Mary's, which was not furnished by other schools. Therefore the clinical field had been widened by affiliation with Paddington Infirmary and Paddington Green Children's Hospital, and arrangements were contemplated with a lying-in hospital which would give the students access to a large number of midwifery beds. For those already qualified a number of scholarships and posts were instituted, so that a man who was keen upon pursuing his studies could "hang on." The post-graduate courses were very important, not merely to the graduates. By means of the criticisms and suggestions of graduates the school learned whether it was giving to students the actual equipment which they would need in practice. The entry to the school this

ear was seventy-one; it had not diminished. Sir John Broadbent proposed the health of the chairman and told the story of his researches upon kala-azar, cholera, dysentery, and amoebic liver abscess. Sir Leonard Rogers, in reply, said that his choice of a profession was determined for him at a very early age. In his native Cornwall the seventh son of a seventh son was regarded as born to be a doctor; he was the seventh son of a sixth son, and that was regarded as near enough for the purpose. The only merit he could claim was that he refused all other work in order to stick to research, breaking with the tradition in India that a pathology post should be used as a stepping stone to lucrative clinical practice.

KING'S COLLEGE HOSPITAL.

The ninety-third winter session of King's College Hospital Medical School opened on October 3rd, when the ceremony at Denmark Hill was presided over by Viscount Hambleden, chairman of the board of management. In his introductory speech the chairman remarked on the great success of the past year, not only in work, but also in play. The enforced closing of some of the hospital wards, owing to shortage of funds, brought various disadvantages, including a considerable loss of clinical material for teaching purposes. A certain number of beds had, however, been opened for the treatment of patients who could contribute the whole cost of their maintenance, and he was glad to know that in the great majority of cases it had been possible to use these beds for teaching purposes. Although 160 beds had been closed, the number of in-patients had not gone down in proportion, because the number of days during which beds were occupied had been reduced. The dean of the medical school, Dr. H. Willoughby Lyle, in his annual report said that there were now 278 undergraduate students, of whom 98 were women.

The introductory address was given by Sir Herbert Jackson, K.B.E., F.R.S., Emeritus Professor of Chemistry in the University of London, who discussed in particular the place of science in education, and insisted on the importance of breadth in the early training of those who intended to follow the medical profession. The time, he thought, had come to consider seriously whether the specialization which had been getting more and more evident even in early education, and was now so pronounced in scientific teaching at the universities, was likely to produce the best result or to be the method by which a student of science at the present day could reap the best results from the work of his predecessors. It seemed necessary to encourage a much wider outlook by the student of science. Recent experience was in favour of decreasing the mass of detail to be accumulated by the student and increasing his opportunities for gaining a wide and sound foundation of knowledge. It was really not a contradiction in terms to say that the broader the earlier education in science as a whole the more complete specialization in any one branch could be made. Moreover, the inclusion of the subjects grouped together under the term "humanities" was vital in the education of one who, like a medical man, entered into intimate relations with his fellow creatures. The outlook on science changed so rapidly, and the applications came one after the other so quickly, that it seemed that a medical man needed a sounder and earlier study of general principles throughout the sciences.

MIDDLESEX HOSPITAL.

The opening of the eighty-eighth winter session of the Middlesex Hospital Medical School took place on October 3rd at Wigmore Hall. In the absence of Princess Alice the prizes were presented by the Earl of Athlone, chairman of the governing body of the hospital. The dean, Mr. A. E. Webb-Johnson, in his report for the past academic year, recorded several munificent gifts to the hospital and school, notably that by Sir William Veno, who had presented £10,000 for cancer research in the form of £1,000 a year for ten years. It had been decided to use this additional income for the development of research in biochemistry with a view to the solution of some of the chemical difficulties of the cancer problem. The financial support received during the past year had encouraged the authorities to make substantial additions to the accommodation in the medical school in order to enlarge the facilities for research.

The introductory address was delivered by Professor Sidney Russ, D.Sc., physicist to the hospital, who devoted a large part of his discourse to the life-work of two English

pioneers in scientific research—William Gilbert and Thomas Young. He reminded his audience that, besides their epoch-making discoveries in physics, both men were successful in the profession of medicine, Gilbert being President of the College of Physicians and Young a Fellow of the College and a physician to St. George's Hospital. Professor Russ feared that there was a disposition nowadays to think of modern discoveries as outstripping in importance those that had preceded them. Pioneers like Gilbert and Young had not only to search out the secrets of nature, but to combat the opposition of the pseudo-science of their day; for that reason their work would always be highly appraised.

The annual dinner of the Medical School was held at the Trocadero Restaurant, with Mr. W. Sampson Handley in the chair. There was a very large company, including many old students. The chairman, in proposing prosperity to the hospital and school, spoke of the excellent progress made in various directions, and declared that the prospect had never been brighter. The toast was replied to by Mr. S. G. Asher, chairman of the school council, who insisted that the hospital and school were one; medical education, research work, and the training of nurses were as much the functions of a hospital like the Middlesex as the actual treatment of the sick. Mr. A. E. Webb-Johnson, who also responded, remarked on the large number of entries this year, and the high proportion of students from Cambridge.

WESTMINSTER HOSPITAL.

The winter session of the Westminster Hospital School of Medicine opened on October 2nd, when Mr. G. T. Mullally, assistant surgeon to the hospital, gave an address on "The art of medicine." The ceremony, which took place in the board room, was presided over by Mr. Walter G. Spencer, senior surgeon, who in the course of a brief sketch of the history of the hospital remarked that it was founded in the days when no such thing as a medical school existed in England. A report of the year's work and successes was presented by the dean, Dr. A. S. Woodward. In his address Mr. Mullally insisted that however scientific medicine might become in the future its practice would always remain an art. Contact with the individual patient was the most important element in clinical studies. The student would soon learn that there was no certainty in medicine—that the practitioner was guided chiefly by the accumulated observations of his predecessors. In medicine there was no final court of appeal; each of them must solve his problems as best he could. It was the human, or perhaps, better still, the living, element which provided at once the difficulty and the charm of medicine. The art of medicine was the choice of the remedies and methods best suited to the individual patient. The patient in feeling that his illness was different from other illnesses was right; thorough realization of that fact was the first principle in the successful practice of medicine. The patients in that hospital kept their names and were not known by numbers; thus they kept their individuality and were the gainers thereby. One of the great dangers in the setting up of a national medical service was that the independent doctor might become an official and the individual patient merely a statistical unit: the art of medicine could not be practised upon units.

The annual dinner of the past and present students of Westminster Hospital was held at the Wharfedale Rooms, Great Central Hotel, on Monday, October 2nd. Ninety-one were present, the guests including Sir Edward Pearson, the chairman of the hospital, Mr. C. M. Power, secretary of the hospital, the Rev. Dr. Hillard, highmaster of St. Paul's School, and Mr. Arnold Powell, headmaster of Epsom College. The toast, "The Hospital and Medical School," was given by the chairman, Mr. Arthur Evans, and responded to by the dean of the medical school, Dr. A. S. Woodward, who described the steady progress in the number of students (the present entry being the highest for fifteen years) and the large number of academical successes. Mr. Walter Spencer proposed "Past and Present Students," in response to which Mr. Rock Carling and Mr. Wilson spoke. Sir James Purves-Stewart gave the toast, "The Visitors," coupled with the names of the highmaster of St. Paul's and the headmaster of Epsom College, both of whom in their replies referred to the long and honourable association of their respective schools with Westminster Hospital. "The Chairman" was given by Sir H. Bryan Donkin, the senior consulting physician.

Scotland.

DIPHTHERIA PREVENTION IN ABERDEEN.

PROFESSOR MATTHEW HAY, medical officer of health for Aberdeen, has submitted a report to the public health committee of Aberdeen Town Council, strongly urging the use of toxin-antitoxin for the prevention of diphtheria. Professor Hay pointed out that during the last few years an extensive trial had been made, more especially in New York, of the method by which small doses of a special diphtheria toxin-antitoxin were used, which, though not producing the full immunizing effect at once, conferred complete protection for many years, and in all probability for a period equal at least in duration to the whole period of childhood. He stated that at the City Hospital, Aberdeen, he had already been using this new method for almost two years for the protection of the staff, with entirely satisfactory results. In New York many thousands of school children had been treated by it without the occurrence of any cases of diphtheria in a child in whom immunization had been properly carried out. Professor Hay suggested that the health department should be authorized, in connexion more especially with mother and child welfare work, and at the City Hospital, to offer gratuitously the toxin-antitoxin treatment against diphtheria on the understanding that it would not be carried out in any case without informing the regular medical attendant of the family and obtaining his acquiescence. No compulsion would in any case be attempted, but an endeavour would be made in the instruction given to mothers at welfare centres and elsewhere to persuade them of the advantages of the treatment.

THE CENSUS OF SCOTLAND, 1921.

County of Ayr.

Continuing the publication of the county census reports in alphabetical order, and following those of Aberdeenshire and Argyllshire noticed in our issue of September 9th (p. 487), the reports on the counties of Ayr and Banff have now been issued. Omitting from calculation the four great towns of Scotland, Ayrshire stands next in population to Lanarkshire. At the census day it had 299,273 inhabitants. But the delay of the census from April to June has appreciably affected the figures for Ayrshire, just as it has those of Argyllshire. The towns on its long coastline from north to south—Largs, Ardrossan, Saltcoats, Irvine, Troon, Prestwick, Ayr, and Girvan—are favourite summer health resorts, the sand dunes along the shore providing many miles of almost contiguous golf courses, some of whose names are of world-wide familiarity to golfers. One incidental result of the change of census date is that Ayr, the county town on the coast, is now shown with a slightly larger population than the inland town of Kilmarnock, which has always hitherto stood first. The Ayr burgh population is shown as 35,763, as against Kilmarnock's 35,747, a difference of 16. The county has shown a steady decennial increase in inhabitants ever since the first census of 1801, when the population was 84,207, so that now it is fully three and a half times as large. Sixteen burghs have 56 per cent. of the population, the non-burghal areas having 44 per cent. The area of the county is 724,251 acres, giving an average of 41 persons per 100 acres. In the burghal portion the average is 1,420, and in the non-burghal 19. Of the burghs, Saltcoats had (in June) 2,905 persons per 100 acres, Kilmarnock 2,799, Galden 2,606, and Largs 2,124. The lowest averages were in some of the parishes of the Carrick, or southern, non-industrial district of the county.

Sex and Age.—The ratio of females to males was 109.3 to 100, as against 106.1 to 100 in 1911, the relatively high increase of females being probably associated with influx of summer visitors. The increase in population is almost entirely over 15 years of age. The average age of males is 27.9, and of females 29.3, as against 26.4 and 27.7 in 1911. Of children under 15, 89.3 per cent. had both parents alive, 6.6 had mother alive but father dead, 2.9 had father alive but mother dead, and 0.6 per cent. had both parents dead. Of males aged 15 and over 41.8 per cent. were single, 53 per cent. married, and 5.2 per cent. widowed. The corresponding figures for females are 41.6, 47.8, and 10.6 per cent.

Housing.—The number of persons per 100 windowed rooms was 156, as against 153 in 1911, but this is doubtless owing to summer visitors, as the ratio had steadily improved from 1861 onwards. In that year it was 238; in 1871, 190; in 1881, 178; in 1891, 166; and in 1901, 157. The total burghal ratio is 156, the same as for the county; but Galden has 190, Kilmarnock 185, Kilmarnock 175, and Irvine 173. Of the total population, 9.3 per cent. lived in one-

roomed houses, 41.5 per cent. in two-roomed, 18.6 per cent. in three-roomed, 9.4 per cent. in four-roomed, 5.4 per cent. in five-roomed, and 4.4 per cent. in six-roomed.

Occupations.—Of the population 12 years old and upwards, 58.9 per cent. had remunerative occupations. The principal, stated as a percentage of the total persons in occupation, were: Mines and quarries, 12.6 per cent.; metals, 11.6 per cent.; commerce (clerks excluded), 9.5 per cent.; agriculture, 9.4 per cent.; personal service, 8.9 per cent.; textiles, 7.7 per cent.; transport and communication, 7.2 per cent. Professional occupations (excluding clerks) were 3.7 per cent.

County of Banff.

The population of this county on the Moray Firth was 57,298, a decrease of 6.7 per cent. since 1911. The county reached its decennial maximum of 64,190 in 1891, having grown steadily from 37,216 in 1801. Of the total population 53.2 per cent. is burghal and 46.8 non-burghal. There are eleven burghs, of which the largest is Buckie with 8,690 inhabitants, and the smallest Dufftown with 1,454. All the burghs have lost population since 1911, and so also have both of the two county districts and every one of 22 parishes. The county area is 403,053 acres, and the average number of persons per 100 acres is 14. The burghal average is 814 and the non-burghal 7. The most sparsely populated parishes are Cabrach and Kirkmichael, each with one person per 100 acres.

Sex and Age.—The proportion of females to males is 109.3 to 100, against 105.4 to 100 in 1911. The average age of males is 28.9 years, and of females 31, against 27.5 and 29.4 in 1911. Of 18,705 children under 15, 85.2 per cent. had both parents alive, 11.6 per cent. had lost one parent, and 2 per cent. had lost both. Of the male population aged 15 and upwards 42.5 per cent. were single, 51.5 married, and 6 widowed or divorced. The corresponding figures for females were 42.5, 47.2, and 12.3 per cent., the number divorced being 7.

Housing.—The average number of persons per house was 4.6. The average number of persons per 100 windowed rooms was 103, as against 166 in 1861, 154 in 1871, 138 in 1891, 128 in 1891, 119 in 1901, and 114 in 1911, showing a steady and satisfactory decrease in room density. The percentage of population living in one-roomed houses was 1.8, in two-roomed 14.7, in three-roomed 22.9, in four-roomed 18.7, in five-roomed 14.9, and in six-roomed 8.9. Only 258 persons in the county can speak Gaelic.

Occupations.—Of the population 12 years and upwards 54.3 per cent. were in remunerative occupations, the principal, stated as a percentage of the total persons in occupations, being—agriculture 26.6, fishermen 13.8, personal service 13, commerce (excluding clerks) 7.4, transport and communication 6.8. Professional occupations (excluding clerks) were 4 per cent.

County of Berwick.

Among the most recent sections of the Census of Scotland, 1921, is that dealing with the border county of Berwick.¹ It had a population of 28,246 on census day, being a decrease of 1,397, or 4.7 per cent., since 1911. The population steadily increased from 1801 to 1861, when it reached 36,613, but since then has steadily decreased, being now 22.9 per cent. less than the maximum. Of the total population only 22.7 is burghal, and the four burghs are little more than villages, the largest being the fishing town of Eyemouth with 2,477 inhabitants, and the smallest Lauder with 759. Duns, with a population of 1,868, is the capital of the county, the town of Berwick-on-Tweed being uniquely regarded, since the union of England and Scotland, as neither in the one country nor the other, though municipally it is English, with a mayor and aldermen instead of a provost and bailies. The area of the county is 292,535 acres, giving an average of 10 persons per 100 acres. The proportion of females to males is 110.1 to 100, against 108.9 to 100 in 1911. The average age of males is 32.4 years, and of females 34 years, as against 30.3 and 32.1 in 1911, showing an average increase of two years. Of males 15 years and over, 40.8 per cent. were single, 51.9 per cent. married, and 7.3 per cent. widowed or divorced. The corresponding figures for females were 43.5, 46.0, and 10.5 per cent.

The average number of persons per house was 4, against 4.2 in 1911. The ratio of persons per 100 windowed rooms was 101. In 1861 it was 165; in 1871, 147; in 1881, 133; in 1891, 118; in 1901, 113; in 1911, 103; and now 101. Of the total population, 3.3 per cent. lived in one-roomed houses, 29.3 in two-roomed, 22 in three-roomed, 16.8 in four-roomed, 7.1 in five-roomed, and 4.9 per cent. in six-roomed. Of the population of 12 years and upwards, 92.1 per cent. of males and 29.5 per cent. of females were in remunerative occupations, the principal, stated as a percentage of total occupations, being—agriculture 39.5 per cent., personal service 11.3 commerce (clerks excluded) 6.5, transport and communication 6, and fishermen 4.4 per cent.

THE CALEDONIAN MEDICAL SOCIETY.

The Caledonian Medical Society held its annual dinner this year in London. It took place on September 29th at the Hotel Cecil, and the President, Dr. John Matheson of Islington, was in the chair. Sir James Cantlie gave the toast of "Caledonia" in a doric not wholly intelligible to some of the guests, and incidentally alleged that the language of Chaucer was still spoken in Teviotdale. He asserted that the Scots and the Swiss were the only peoples to suffer from nostalgia, and maintained that the cure of that complaint was effected by joining together in societies, of which the Caledonian Medical Society was an example. The Society had the widest circle of any medical body in the kingdom, and herein it was significant of the Scot, whose name came from *scute*, a wanderer. The Rev. Alexander Macrae proposed the toast of the Society, and was forthwith elected an honorary member. He told how it fell to the lot of the parson to fortify the doctor's advice, and occasionally to sympathize with the patient against it. The President, in responding, said that the medical profession everywhere was a vast freemasonry, to which the Caledonian Medical Society contributed its share. Its numbers were small, but its geographical distribution was as wide as the world, and thus it was a microcosm of the Scottish nation. The health of the guests was entrusted to Sir John Collio, who told some Scottish stories. Sir Donald Maclean, M.P., in acknowledging the compliment, said that in recent years the medical profession had made greater strides in its development and outlook than any other learned profession, and the well-being of civilized communities and the uplifting of communities not civilized depended in a major degree on the devotion and scientific mind of the doctor. On that account it was increasingly necessary that the government of all countries should see that the medical profession was thoroughly well equipped for its fight against disease. When he had been asked recently to name the most useful classes in the community he replied, "Doctors, policemen, and ministers, and in that order." He did not know that adequate record had been made of the services of the medical profession in the war. There the medical men shirked nothing, and through all the horrors and excitements carried the calmness of the scientist and the sympathy of the Samaritan. He trusted that circumstances would not arise to make such a call upon the profession necessary again. Sir Dawson Williams, who also responded, said that in his calling he always found it a great satisfaction to deal with a Scotsman because the Scotsman was commonly something of a philosopher, and, despite all that was said to the contrary, had usually a keen sense of humour. The gathering broke up after honouring the President, on the motion of Dr. G. C. Anderson, who said that Dr. Matheson's forty years in London had not obscured one of the natural characteristics of the Scotsman. Dr. Matheson replied by saying how much the society was indebted to Dr. Anderson and Dr. Campbell McClure for the success of the occasion.

ANDERSON COLLEGE OF MEDICINE.

The vacancies on the teaching staff of the Anderson College of Medicine, Glasgow, to which we made reference in our issue of September 23rd, have now been filled. Dr. James H. Martin has been appointed to the chair of midwifery and diseases of women, and Dr. George B. Brand to the lectureship on diseases of the throat and nose. At their meeting the Governors resolved to invite the late Dean of the Medical Faculty, Dr. John Macintyre, to join the board on his resignation after thirty-one years' service on the teaching staff of the College.

England and Wales.

AN ORTHOPAEDIC SPORTS MEETING.

A sports meeting of more than ordinary interest was held at Grangehorpe Hospital, Manchester, on September 15th, when limbless men demonstrated how it was possible to overcome the handicap of a missing limb and to participate in sports. The meeting was organized by Dr. F. A. Hort, medical superintendent of the hospital, and among the entrants were a number of men who are members of the North of England Limbless Sporting Club, which was organized by Dr. Hort when he was in Snoderland. The sports meeting was opened by Lord Haig, who paid a tribute

to what the medical profession had done during the war and since in alleviating the sufferings of wounded and disabled men, and expressed the hope that such gatherings as that would encourage the men to make the fullest use of the artificial limbs. The sports were not arranged primarily as an exhibition, but in the belief that they would furnish data for carrying the present methods of using artificial limbs to an even further point of success. The handicapping committee included not only well-known Manchester sportsmen, but the professor of anatomy and the professor of physiology at Manchester University, orthopaedic surgeons, and others.

MEDICAL ARRANGEMENTS AT A GARDEN FACTORY.

The firm of Cadbury Brothers is well known as one of the pioneers of the industrial garden city, for their chocolate factory was moved from the heart of Birmingham to a country district outside so long ago as 1879, and the town of Bourneville, carefully planned, has grown up around it. The health of the industrial worker received perhaps closer general attention in the later years of the war than ever before, and the measures adopted by this firm to maintain the health of their workpeople are of interest. Encouragement is given to athletics of every kind, and facilities for physical culture and recreation are provided. There is a medical staff of two full-time medical practitioners, one a lady, and four qualified nurses are attached to the surgery, three of them qualified masseuses. Before engagement every applicant's medical history is studied, a thorough medical examination is made, and the medical examiner may suggest the type of work most suitable. Special measures may also be recommended, such as a course in the remedial gymnasium with periodical re-examinations. All cases of sudden illness at work are seen by a medical officer, and if continued medical attention is necessary the patient may be attended either by his private doctor or by the works doctor, and also by the works nurse. In addition to advice, treatment, and medicine, the works doctor may authorize the free supply from the dispensary of extra nourishment. All accidents are immediately reported and prompt attention given, in trifling cases by members of the works ambulance, and in more serious cases by the works doctors. The works doctors are co-opted members of the Accidents Committee of the Works Council, which investigates all accidents, apportions blame, if any; takes steps to prevent a recurrence; and decides whether compensation shall be paid. Particulars of the symptoms of tuberculosis are circulated in the works, and employees who suspect its presence are encouraged to visit the works doctors, emphasis being laid on the necessity for early treatment. The firm maintains two convalescent homes, which are used not only for those recovering from illness but also to give a change of air and a rest to those threatened with breakdown. Three whole-time dentists are employed, together with two mechanics and four attendants, and as part of the preliminary medical examination all applicants for work are examined by one of the dentists, and a record is kept of the oral condition of those under the age of 16. It is a condition of employment that all who enter the works under 18 years of age shall have such dental treatment as is considered necessary by the works dentists.

Correspondence.

THE LEGIBILITY OF PRINTED MATTER.

SIR,—Your annotation on the above subject in the JOURNAL of September 23rd (p. 570) prompts me to draw your attention to a far more serious matter than the legibility of printed words, and that is that of printed figures. Whereas the association of ideas enables us to guess fairly accurately the probable sequence of words, with figures the case is vastly different. Errors in reading figures, whether of money or statistics, may lead to disaster. It is therefore very important in the interests of both old and young that there should be no possibility of mistaking one figure for another.

The ends of figures having open loops, such as 2, 3, and 5, should not be curled up; such turning makes these figures somewhat like an 8. In 4 the oblique stroke should be thicker, as, in indifferent light, it might be mistaken for a 1. So figures with tails—6, 7, and 9—should have these strokes prolonged above or below the line respectively; a 6 or 9 with its ends curled in is easily mistaken for an 8.

I see in the text of our JOURNAL many of the figures conform to my suggestions.

Would it not be possible for a committee to be called together composed of typefounders and printers with the view to authorizing a standardization of figures?—I am, etc.,
Chichester, Sept. 28th.
HERWOOD SMITH.

INHERITANCE AND MENTAL DEFECT.

SIR,—We must, I think, concede Sir Archdall Reid's contention that nothing but predispositions to produce characters in response to fitting nurture can be inherited. In that case, obviously, all characters, as distinguished from likenesses and differences between individuals, are equally innate, acquired, and inherited.

But if the Mendelians are right and there is alternate inheritance (not merely alternate reproduction), his axiom, that "variations are the sole cause of non-inheritance; apart from variations, like begets like when parent and offspring develop under like conditions of nurture," does not nearly cover the whole field of study.

According to Mendelian doctrine, which is supported by an immense amount of experimental work, inheritance, in any given particular, tends to be from one ancestor only. In that case there remains an enormous field for research—a field larger than that covered by his axiom.

In his letter (August 26th) he stated that blending is universal, but he gives little evidence in support of an opinion which is opposed to much considered belief.—I am, etc.,
Chesham Bois, Bucks, Sept. 28th.

W. BASTIAN,
Surgeon Commander R.N.

EXPERT WITNESSES: SURGICAL AND MEDICAL.

SIR,—In common with every qualified practitioner, I welcome the very restrained and common sense letters of Mr. C. H. Fagge and Sir John Lynn-Thomas. I hope the British Medical Association will take up a strong attitude on this question. The *fons et origo* is here ultimately between the actively increasing knowledge of medicine and surgery, and very, very ancient methods of law which should be obsolete, and do not, spell justice. The present occasion is "fractures"; perhaps even more of an anachronism exists in the medical and legal aspect of mental disease.

It is time that legally qualified practitioners were absolved from a lot of useless anxiety. Law should mean justice, and the period between variation and the Ark should be definitely determined.—I am, etc.,
Sevenoaks, Oct. 1st.

GERALD SICHEL.

A CASE OF SUPPOSED SUPERFOETATION.

SIR,—The following case seems to be of some interest:

The patient was a primipara whose last menstruation had commenced on May 9th. I saw her on January 10th and found a transverse lie, which was easily dealt with by external version. Labour started at 11.30 p.m. on February 11th and a baby weighing 11½ lb. was delivered with the help of forceps at 6 p.m. on the 12th. The placenta and membranes came away quite complete. No abnormality of cervix or uterus was observed. On February 13th and 14th she was quite well.

On February 15th the nurse informed me that pressure on the fundus caused something to bulge into the vagina. I found that she was quite correct, and with a pair of dressing forceps I removed from the vagina a complete bag of membranes containing a small foetus, which seemed to be quite fresh and showed no sign of any decomposition, mummification, or dehydration. I sent the specimen to Dr. J. D. Barris of St. Bartholomew's Hospital, who has kindly informed me that he considers the age of the foetus to be about 16 weeks. He is keeping it for the hospital museum.

Is this to be regarded as a case of twin pregnancy with one blighted ovum or as a genuine case of superfoetation? Against the former is the fact that the ovum seemed to be quite normal; against the latter that the patient does not appear to have menstruated during the nine months preceding the accouchement.—I am, etc.,
Alexandria, Egypt.

E. N. RUSSELL,
M.D., B.Ch. Cantab.

UNSUSPECTED PREGNANCY.

SIR,—Dr. Fletcher and Dr. Williams have each contributed one case of this condition, and one case is all that a practitioner is likely to see, however long his experience.

Rightly to appreciate the cases to which these gentlemen refer, I, and I think we, require a little more information, because certain circumstances are necessary to bring about such a result.

A full-time undiagnosed pregnancy presupposes (a) a regular cervical menstruation, and (b) a large woman or (c) a small child (this word to include all the contents of the uterus).

I also, in thirty years' slavery as an accoucheur, only met one case of "unsuspected" pregnancy. She was a very large woman, and quite as stupid as her husband, who applied turpentine stupes in an idle attempt to stop the pains. In this case there was no reason to question the *bona fides* of the mother, because she had been married sixteen years, it was her first child, she was living with her husband (this latter statement should be underlined), and she was obviously delighted with the result of her labour; but given a woman of average size, with uterine contents of average bulk, I have no hesitation in asserting that she cannot go to full time without suspecting her condition.

Perhaps your correspondents will be good enough to inform me as to the points I have raised, and thus add to the value of their communications.—I am, etc.,
London, W., Oct. 2nd.

GRAHAM GRANT.

EMETINE INJECTIONS.

SIR,—It does not appear to be generally recognized that the precautions which are usually adopted to safeguard against local reaction where an injection of strychnine is given hypodermically are inadequate where emetine hydrochloride is administered by repeated injection. I have found that, even when doses of from 1/2 to 1½ grains are given on alternate days for a complete month (as is generally necessary to produce a permanent cure for schistosomiasis with this drug) the commonly experienced local pain from emetine injections can be avoided (1) by using only reliable preparations of emetine; (2) by giving the injection intramuscularly instead of subcutaneously; (3) by dissolving the tablet in a boiling solution of 1 per cent. carbolic acid immediately before injecting the dose; (4) by having a good supply of reliable needles. To avoid unnecessary trouble, it has been my practice to boil my hypodermic syringe and needle in this solution within its metal case, usually over a spirit lamp; the tablet quickly dissolves when 1 c.cm. of this hot solution is drawn up into the syringe, and some rectified spirit may be used, both to render the site of the injection slightly anaesthetic and antiseptic and to cleanse the syringe and needle before they are returned dry to the case. The addition of this weak solution of carbolic acid does not alter the character of the drug and is certainly very gratifying to the patient, whose condition may be too much impaired by the presence of the numerous parasites of amoebic dysentery or bilharzia disease to stand the risks of local sepsis.—I am, etc.,
Durban, Aug. 31st.

F. G. CAWSTON, M.D. Cantab.

THE RADICAL PREVENTION OF VENEREAL DISEASE.

SIR,—It is the looker-on who sees most of the game. In the present controversy both sides are right—and wrong. The umpire's decision, as usual, will please neither side.

Obviously, prevention by disinfection is sound in principle. If every potential sinner is taught in advance to disinfect properly and promptly enough, and does so, venereal disease will cease. That is quite clear. Obviously, too, prevention by moral suasion is sound. If every potential sinner is taught in advance such a dread of venereal disease that he (or she) abstains from illicit union, syphilis and gonorrhoea will vanish. That is equally unquestionable.

Both methods are sound—in theory. Both methods are failures—in practice. Neither method is radical enough. Each fails for the same reason—because human nature is what it is.

Disinfection falls short in practice because men are not saints. It demands a certain degree of unselfishness from the average sinner—or at least some selfish prudence. And the average sinner falls short of the requirements. He forgets, or he "imbibes," or he "won't be bothered." Even in the army such failures are numerous. Will the failures be less in civil life?

Moral propaganda based on fear of consequences fails in practice because men are human. The motive appealed to is mostly a selfish one; and you will not make a man unselfish from a selfish motive! To abstain from doing what you think it is right to do, from selfish fear, is cowardly. It is not working upon a man's higher instincts. Such an appeal is pitched too low to be effective.

Once again, disinfection fails because it is not radical enough: it is too superficial in its action; it must penetrate deeper than the epithelial surface. It must reach the cells of the cerebral cortex; the centres controlling genital impulses stand in need of purification as much as the more external genital organs.

In the same way, moral suasion by means of fear fails because it is not sufficiently thorough. To ensure success it must be applied in the thoroughgoing fashion of the Zulus. In the days before Britain tampered with them the Zulus were a more moral people than we. The penalty of illicit intercourse was death, and it was enforced. Illicit unions were not numerous in Zululand. Unless applied in this thoroughgoing style the moral propaganda based on fear of consequences will fail. It did with the Jews. Moses commanded that the adulterer and adulteress be both stoned. But we find, some centuries later, that though a certain Jewish adulteress was brought up for condemnation her male fellow sinner seems to have gone free, and none of her male accusers could claim the right to throw stones at her. The Jews were more one-sided than the Zulus in the enforcement of their law. Such lax, one-sided application of the moral method is foredoomed to failure.

With both the sexual sinner and the moralist the real trouble is an arrest of development. The sexual sinner suffers from arrested development of the sex instinct. In his case an animal lust for the female has not developed into a human, humane love for woman. His sex instinct is still subhuman; it has not evolved beyond the selfish, antisocial stage to its normal "sublimation" in humane, social instincts. The moralist, whose propaganda depends on fear—whether of punishment or of other consequences—suffers from arrested development of his morality. He is still—morally—in the "Mosaic dispensation." His propaganda is pre-Christian in principle. He makes the selfish sinner more selfish still by cultivating selfish fears. His moral methods are, to that extent, Mosaic.

Thus we arrive at this paradox: the method of external disinfection fails in practice because it asks too much of human nature; it requires men never to be careless, or lazy, or drunk. The "Mosaic" moralist's method fails in practice because he asks too little of human nature; he asks a man to cease from one selfish habit for fear of consequences, instead of asking him to cease from all selfish habits for love of his neighbour.

The onlooker finds the results, on both sides, poor and disappointing. So much energy, so much argument, so much controversy, and so very little progress! An almost pathetic letter on this subject appeared in the BRITISH MEDICAL JOURNAL some months ago, expressing a sense of the ineffectiveness of all methods hitherto adopted. Its writer lamented the slowness of results from the moral propaganda of Moses and St. Paul; more rapid remedies were called for in his view; personally he recommended "rubber sheaths of good material" as the best preventive. His medical qualifications were above the average: his sense of humour hardly equalled them.

Let us do justice to St. Paul: he lamented the failure of Moses more deeply than any of us. He claimed that his own psychological principles produced far more hopeful results. His mode of preventing illicit unions was totally different. The "circumcision" he advocated was a far more radical operation than that of his Jewish predecessors. It is the most radical, as well as the most rational, way of preventing venereal disease. Moses commanded the removal of the foreskin. St. Paul superseded this by a "circumcision of the heart"—the excision of all selfish impulses. Cure selfishness and you prevent syphilis. For after all, sexual sins are but one of the many symptoms arising from that chronic infection—selfish-mindedness. Private passions must be dominated by a passionate public-mindedness. Sexual sin must be remedied by the normal sublimation of the sexual instinct. St. Paul's argument runs somewhat on the following lines:

"Abnormal actions proceed from abnormal thoughts." Disinfect the thoughts and the actions will look after themselves. Sexual sin, like money-grubbing, is merely a manifestation of a selfish mind. (It is interesting to note in this connexion that St. Paul classes the fornicator and the money-grubber together; both are outsiders, self-excluded from "the Kingdom" by their selfish-mindedness.) Further, habit can be overcome by counter-habit. Selfishness can be conquered—inhibited—by a constant habit of unselfish thinking. Moses had treated separate symptoms unselfishly. St. Paul dealt radically with the disease itself. He proved that it is more effectual to attack all sins than one sin. Obviously, if you can teach men a habit of thinking unselfishly in regard to everything, selfishness will vanish in all its various forms, whether sexual or otherwise. He who loves his neighbour will not make a prostitute of her. A universally applied habit of unselfish thinking—practised every day in every way—will get stronger and stronger, and inevitably dominate all the "weedy" habits, or wild oats, of weaker growth. Man of all creatures has an unequalled faculty for acquiring new aptitudes. Hereditary vices, or weaknesses of disposition, will stand no chance against an acquired aptitude of unselfish thinking—a public-mindedness—which operates every minute of every day, increasing in power by constant exercise. The tendency to think unselfishly is no foreign importation: it is native to the soil of the human mind. It is present in every

individual, as is evident if a stimulus be applied of sufficient strength. It has been cultivated so as to control and subdue all the vicious weeds of the mind—with oats included. It has been done successfully in thousands of cases, in every century of the Christian era, by ordinary people. They were most of them pupils of St. Paul, or his colleagues, or of later teachers who had grasped something of his method and principles. For, in his post-graduate days, St. Paul had discovered an "emotional stimulus to morality" that proved surprisingly successful. It is the most radical preventive of venereal disease yet discovered. But the details of its application lie outside the province of a medical journal. As psychologists, however, we know that any moral propaganda without an adequate emotional stimulus is fundamentally feeble and ineffectual.

Are these principles obsolete? Are they too slow of result to be considered by practical modern scientists? Must they give place to calomel cream, or "rubber sheaths of good material"? Possibly a compromise, or combination of methods, may prove the wisest course. In order to estimate their comparative value let us apply the historical test:

1. External disinfection: tried for several years, with special zeal in some parts of Germany. Result, disappointing. By-product—lowered moral standard.
2. Rubber sheaths: tried for some ninety years, especially in France. Result, disappointing. By-product—slow national suicide.
3. Mosaic moral suasion: tried for some nine hundred years or more, especially in Palestine. Result, inadequate. By-product—pharisaism.
4. Pauline psychological method—"circumcision of the heart": tried for nearly nineteen centuries in most European countries. Result, disappointing and inadequate to modern idealists; still, under all the circumstances, rather a surprising success. By-product—the difference in morals between the first and twentieth centuries A.D.

We must leave it to the historians to measure that difference. In our pessimistic moments we are apt to underestimate it. Of these four competing methods, which would a wise reformer seek to reinforce? Which method will prove, in the long run, the most effectual? Which will promote "the greatest good of the greatest number"?

Two reflections present themselves to the moral idealist here. More haste may mean less speed. The method that appears most rapid may prove a deceptive short cut, bringing us to a destination neither anticipated nor desired. If, by a propaganda of external disinfection, we enable men to escape syphilis, at the cost of depraving their sexual instinct and weakening their self-control, have we done more harm than good to the individual? Is society in the end benefited by the net result? Perhaps after all St. Paul's slower radical method may prove the most rapid as well as the most rational.

Meantime we must compromise to some extent. External disinfection has its due place. So long as there are unfortunate individuals among us in whose upbringing St. Paul's radical operation was omitted or inadequately done: so long as there are those whose sexual instinct has had its development arrested at a subhuman level: so long as there are social failures who make prostitutes of other men's sisters—external disinfection should be practised by all such. It is their duty to society, and we must hope that they will have retained enough of a conscience to do it. It is the least these weaker brethren can do if they have any decency left. Even though they should succeed in washing the last spirochaete or gonococcus off their external genitals, the internal centres are not greatly benefited; the mind remains as selfish, as sensual, as semi-civilized as ever: their thoughts are filthy still.

Let the moralist, however, beware in his turn lest he sin from too much zeal and fall into a censorious pharisaism. Who are we to cast stones? Are any of us without sin when judged by the post-Mosaic standard? That standard is a severe one, and its searching relentlessness may well disarm criticism of our weaker brethren. For the post-Mosaic standard of sexual morality has been put in these words: "Whosoever looketh on a woman to lust after her hath committed adultery with her already in his heart." Judged by that standard, how many of us are entitled to cast a stone at any other sinner? Even a "moral idealist" must hold his hand and make his apology to his fellows if his criticism of himself and them has at all savoured of pharisaism. With that apology, therefore, these reflections on a vital question are submitted for consideration.—I am, etc.,

—Sheffield, Sept. 22nd.

HERBERT CAIGER.

THE THYROID GLAND AND DISEASED TONSILS.

SIR.—Dr. H. Crichton Miller's most interesting paper on the psychic and endocrine factors in functional disorders, published in the JOURNAL of September 23rd, 1922, contains a paragraph on page 552 which I venture to think needs elucidation.

Speaking of "the chronic colds and sore throats . . . which culminate in a belated enucleation of tonsils," he asks, "How

often does a laryngologist in such circumstances stop to think of the once efficient thyroid now morphologically altered beyond repair?"

Are we to assume that the enucleation is followed by injury to the thyroid as a direct result of the operative interference?—I am, etc.,

September 23th.

M.A., M.D.

Obituary.

W. S. HALSTED, M.D., F.R.C.S. ENG. and EDIN.,
Professor of Surgery, Johns Hopkins University, Baltimore.

THE death is announced of Dr. William Stewart Halsted, professor of surgery at Johns Hopkins University, Baltimore, since 1889. He was born in 1852, and graduated in New York in 1877. He was an honorary Fellow of the Royal Colleges of Surgeons of England and of Edinburgh; he received the honorary degree of LL.D. from Yale in 1904 and from Edinburgh in 1905, and the honorary degree of D.Sc. from Columbia University in 1904. He was one of the pioneers of modern surgery in America, and his name will always be remembered in connexion with the Johns Hopkins Hospital, the foundations of whose reputation were laid by Osler, Welch, Kelly, and Halsted. In 1907 a portrait group of those four friends, painted by Mr. J. S. Sargent, R.A., was presented to the hospital.

Besides many other contributions to surgery there are four subjects upon which Dr. Halsted made important observations. The modern operation for cancer of the breast was instituted by Mitchell Banks of Liverpool. His first paper was published in 1877, a second in 1882, and a third in 1887; amongst other things he advocated a circular incision, undercutting the skin, the removal of the pectoral fascia and lower part of the pectoralis, as well as the axillary glands, whether enlarged or not. In this he was opposed by some of the most prominent London surgeons. In his Lottsonian lectures to the Medical Society (BRITISH MEDICAL JOURNAL, 1900, i, 557) he stated that of 213 cases treated by the method he advised some 67 were alive three to twenty years later, and that among the last sixty operations there had been no deaths. Heidenhain (*Langenbeck's Archiv*, 1889) and Stiles (*Edinburgh Medical Journal*, 1892), gave a more exact description of the lymphatic system connected with the breast, which has served as a guide in connexion with the question of what should of necessity be removed. Halsted commenced his contributions to the subject in 1889 by proposing that the pectoralis major should be completely removed in every case, and that the supraclavicular glands should be excised after division of the clavicle. Later on, however, Halsted himself gave up the division of the clavicle, and excision of supraclavicular is an exceptional and generally unsuccessful addition to the operation; surgeons now remove the pectoralis major except the clavicular portion. In Deaver's work (Deaver, McFarland, and Herman, *The Breast: Its Anomalies, its Diseases and their Treatment*, 1918) is included a table of cases operated on by Halsted. There were 204 operations; 13 patients were lost sight of; of the 191 reported on 39 (20 per cent.) were alive and well five years after the excision, 10 had died within the five years without recurrence, and 10 had died of metastases over five years after the excision.

Halsted was a pioneer in the use of rubber gloves when operating. Cotton gloves had previously been recommended, by Mikulicz-Radecki of Breslau in particular, and in spite of drawbacks had been widely adopted by surgeons when, in 1890, Halsted advised rubber gloves, the making of which he superintended so that a workmanlike article was produced and was generally adopted. The introduction of antiseptic surgery by Lister rendered the radical treatment of hernia practicable. Attention was particularly concentrated upon the removal of the sac. A method of doing this was described by Sir W. MacEwen of Glasgow (*Annals of Surgery*, 1886, iv, 87). In 1887 the late Mr. Arthur Barker (BRITISH MEDICAL JOURNAL, 1887, ii, December 3rd) described the method now commonly used of ligaturing the neck, and after cutting away the sac fixing the stump within the internal ring. In 1884 Bassini, believing that recurrence of hernia after operation was due to yielding of the transversalis fascia, had suggested that this might be obviated by suturing the internal oblique and transversalis muscles behind the spermatic cord; he described 100 cases in 1883 (*Ital. Chir. Cong.*, Napoli, 1883). Halsted in 1880 (BRITISH MEDICAL JOURNAL, 1890, i, 495) went farther and sutured the aponeurosis of the external oblique as well

under the cord, after excision of the sac. This method, however, under the cord, after excision of the sac, was thus rendered tender. Atrophy of the testis also was apt to follow, and O'Connor in 1898 said this happened in 20 per cent. There proved to be a special tendency also to hydrocele after Bassini's operation, as well as after Halsted's modification, and surgeons generally reserve the procedure for direct hernia.

In 1920 Halsted published in the *Johns Hopkins Hospital Reports*, vol. xxi, a treatise on "Ligations of the first part of the left subclavian artery"; the main point of the paper was that the operation demands the highest anatomical knowledge and surgical skill on the part of the surgeon, owing to the multiplicity of important structures behind the origin of the left sterno-mastoid muscle. Halsted's first operation was performed in 1892, and was accompanied by excision of the subclavian aneurysm; the operation had been performed unsuccessfully four times before; Halsted's patient was cured. His second operation (also successful) was performed in 1918. The first case to be successful in this country was operated upon by Charles Stonham in 1893, and the man was shown to the Clinical Section of the Royal Society of Medicine in 1921, twenty-two years after the operation.

We are indebted to Sir BERKELEY MOYNIHAN, Bt., for the following tribute to Dr. Halsted:

The death of Dr. W. S. Halsted removes one of the greatest of American surgeons. Trained as an anatomist, he took to surgery, its science and its art, with great and eager enthusiasm at the time of the inauguration of Johns Hopkins Hospital. Osler, Welch, Howard Kelly, and Halsted were the heads of the departments when the work of that hospital began; the services of each of them have been of the highest order, and it is probably true to say that their association together in those early days has been the means of developing there the authentic spirit of scientific medicine, as truly and as speedily as in any other hospital in the world. Halsted appeared to be the most reticent of the four. His struggles in his younger days, against ill health won the respectful admiration of all his friends, of those more especially who knew how grim and arduous the conflict was. Soon after his appointment to Baltimore he began to surround himself with pupils, whom he trained by the example of his own surrender and devotion to the infinite toil of surgical work, both on the side of research and on that of its clinical practice.

It may justly be claimed for him that he introduced many of the technical methods now embodied in the everyday work of surgeons throughout the world; that he established principles for the proper conduct of operations hitherto performed in a haphazard or perfunctory manner; and that he trained and influenced men who are now teaching the whole world, and carrying out in many schools the ideals with which he first inspired them. Crile, a superb master of the craft of surgery, and a great disturber of intellectual traffic has said that he owes more to Halsted than to any man. Harvey Cushing, unsurpassed in exquisite perfection of technical work and unequalled in breadth and depth of surgical knowledge of the nervous system, and Finney, one of the wisest of men, of wide experience and profound sagacity, both own Halsted as their master. Bloodgood, at least as learned in pathology as any surgeon of the day, was taught and guided by Halsted, and Young, among the most skillful and deft of urologists, learnt his first principles under the same inspiring teacher. If a man's greatest gift to surgery is the number of the pupils trained by him in the highest ideals of research and of practice, then for Halsted there may justly be claimed a place among the most eminent surgeons of the time.

His name will long be associated with the surgery of hernia, of cancer of the breast, of the thyroid and parathyroid glands, and of the vascular system. On all of these subjects he wrote with an authority derived in part from the most patient research, both experimental and clinical, and in part from an operative experience that, in his own hands and in those of his assistants, became stupendous. As an operator he was exceedingly patient and careful. It was he who first used rubber gloves and who then set the fashion for all the world. His method of dissection, of frequent light, swift, sparing movements with the sharpest of knives, instead of the free, heavy-handed deep cutting, of no haemorrhage or the minimum of haemorrhage instead of the severance of many vessels, each bleeding freely until clipped, has become a part of the ritual of the great surgical artists of the day. His method required time, but it was results and not the

no taken to win them that he counted. It was said in jest that if you wanted to watch Halsted perform a radical operation for cancer of the breast, you must hurry away from breakfast to see him and take your lunch with you. But he lost few cases, and the proportion of "cures" from his very extensive and minutely accurate operation was taken as the standard of the best that surgery could do.

He has joined the immortals. For it is certain that so long as the craft of surgery is practised some of the principles which he was the first to formulate, and some of the technical methods which he was the first to devise and to make perfect, will be a part of the creed and of the daily ritual of every man.

THE LATE SIR JAMES AFFLECK.

DR. WM. MURRAY CAIRNS, C.B.E. (Liverpool), sends the following tribute as a supplement to the obituary notice published in our column last week (p. 617):

To his old students, scattered over the whole world, the news of the death of Sir James Affleck will bring a deep pang of loss, for to an innumerable host of our profession he was a veritable father in medicine; nay more, to multitudes of his fellow men—colleagues, students, patients, friends—there was in every truth the beloved physician. Efficiency, sympathy, modesty were outstanding characteristics. His professional ability was evident in all the departments—and they were many—of his work. But it was as a teacher, and especially as a clinical teacher, that he shone. He had a quiet but eminently effective way of combining his personality with his teaching, and of so impressing these upon his students that they could never forget the one or the other. For example, thirty years ago, in his incomparable clinics, he used to say to us students, "When you become practitioners, examine the heart of every patient who consults you, whatever the patient is complaining of; do this always: never omit it." And last week, when I was north, I paid a visit to Edinburgh, partly to see again my old teacher. During our stay I took opportunity to say to him that, literally, in my consulting-room, now "thirty years on," I think of him every day, and, remembering these words of his, I do as he enjoined upon us. Many of us now teachers ourselves gratefully remember how he would take us to a bedside and would point out the significance of a posture, of a movement, of an expression of the face, of the patient. And not only in these, but in other ways innumerable, I shall ever hold myself a debtor to this shy, quiet, unassuming man who, with all his shyness and reserve, was a moulder of men, and who, by his quiet, forceful personality, made an indelible imprint on the life and work of a great company of those who, like myself, are proud to say "I was once his student."

The funeral took place at the Dean Cemetery, Edinburgh, on September 28th. In addition to near relatives, the pallbearers included Sir Harold Stiles, representing the University of Edinburgh, Dr. James Stewart Fowler, representing the Royal College of Physicians of Edinburgh, Sir Joseph Fayrer, representing the Edinburgh Royal Infirmary, and Sir Henry Cook, chairman of the board of directors of the Longwood Hospital for Incurables. Among those who attended the funeral were Sir David Wallace, president, Dr. George Mackay, vice-president, and Mr. Alexander Miles, secretary and treasurer, representing the Royal College of Surgeons of Edinburgh; Dr. Byrom Bramwell, representing the Royal Hospital for Sick Children; Dr. Harry Rainy, vice-president, also representing Sir Robert Philip, president, of the Royal College of Physicians of Edinburgh; Dr. Dawson Turner, Dr. Alexander James, Dr. W. T. Ritchie, Dr. Arthur Sinclair, Dr. Allan Gray, Dr. William Stewart, Dr. James Ritchie.

We regret to announce the sudden death of Dr. JOHN SCOTT TEW at his residence, Brook House, Tonbridge, Kent, on September 27th. He received his medical education at University College, London, and the University of Durham, and obtained the diplomas of L.S.A. in 1880 and M.R.C.S. Eng. in 1881. After taking the D.P.H. Camb. in 1887 he graduated M.B., B.S. Durham in 1889, proceeding to the M.D. degree in 1891. Dr. Tew was also a barrister-at-law of the Inner Temple. He had held the posts of assistant demonstrator of anatomy in the University of Durham College of Medicine, and medical officer of health for the Basford Urban District. In 1895 he went to live at Tonbridge on his appointment as medical officer of health for the West Kent Combined Districts, and medical officer to the Tonbridge Wells,

Tonbridge, and Southboro' Joint Hospital Board. Since 1909 he had held a commission as sanitary officer with the rank of major in the R.A.M.C., Territorial Force. Dr. Tew was a member of the Tonbridge Wells Division of the British Medical Association; a Fellow of the Society of Medical Officers of Health, and a former president of the home counties branch; and he had been president of the Nottingham Medico-Chirurgical Society. His kindly tact and genial good nature won him the regard of the many medical practitioners with whom his work brought him in touch, and his death will be mourned by a wide circle of friends and colleagues.

Universities and Colleges.

UNIVERSITY OF OXFORD.

Radcliffe Prize, 1923.—This prize, of the value of £50, will be awarded by the Master and Fellows of University College upon the report of the Examiners (provided a sufficiently deserving memoir be submitted for adjudication) for a memoir, or papers, embodying research in any branch of medical science comprised under the following heads: Human Anatomy, Physiology, Pharmacology, Pathology, Medicine, Surgery, Obstetrics, Gynaecology, Forensic Medicine, Hygiene. The prize is open to all graduates of the University who have proceeded, or are proceeding, to a medical degree in the University. Candidates, at the date of application, shall not be Radcliffe Fellows; but the provision that candidates shall not have exceeded twelve years from the date of passing the last examination for the degree of B.A. is upon this occasion so far suspended as to enable any graduate who was eligible during the years of the war (1915, 1917, 1919), to be eligible for the next ensuing award (1923). Candidates are required to send in their memoirs to the Assistant Registrar on or before Friday, December 1st, 1922. No memoir for which any University Prize has been already awarded can be admitted to competition, nor may the prize be awarded more than once to the same candidate. Tuesday, March 20th, 1923, is the intended date of the award.

UNIVERSITY OF CAMBRIDGE.

The Vice-Chancellor has appointed Sir Hugh K. Anderson, M.D., F.R.S., Master of Gonville and Caius, together with Dr. T. C. Fitzpatrick, President of Queens', and Dr. Peter Giles, Master of Emmanuel, to be deputy Vice-Chancellors.

The following staff appointments have been made in the Natural Science Schools:—Anatomy: Dr. A. B. Appleton, senior demonstrator; Mr. D. G. Reid and Mr. A. Hopkinson, M.B., junior demonstrators; Mr. V. C. Pennell, M.B., additional demonstrator. Physiology: Dr. F. Roberts, junior demonstrator; Mr. T. R. Parsons, additional demonstrator. Comparative Anatomy: Mr. F. A. Potts, demonstrator. Botany: Mr. J. Walton, junior demonstrator.

UNIVERSITY OF LONDON.

LONDON HOSPITAL MEDICAL COLLEGE.

The Price entrance scholarship in anatomy and physiology offered by the London Hospital Medical College, and open to students of the Universities of Oxford and Cambridge, has been awarded to Mr. J. Gray, of Fitzwilliam Hall, University of Cambridge.

UNIVERSITY OF DURHAM.

At a convocation held on September 23rd the following medical degrees were conferred:

M.D.—J. M. Gover.
M.B. B.S.—H. Moray, S. Bell, G. A. Mason.

The Services.

HONOURS.

Colonel James Muir Crawford, I.M.S., Major (temporary Lieut.-Colonel) Henry Ross, I.M.S.

FOREIGN DECORATIONS.

The following are among the decorations awarded by the Allied Powers indicated for distinguished services rendered during the war 1914-19:

President of United States of America.—Distinguished Service Medal: Major-General Sir William G. Macpherson, K.C.M.G., C.B., late A.M.S. **King of the Belgians.**—Ordre de Leopold (Officer): Colonel Arthur M. Connell, T.D. (Territorial Force, retired). **President of the F.**—Vermelt of the F. **King of Italy.**—Or. (temporary Colonel) Jan. **King of Rumania.**—Ol. **King of the Serbs, Croats and Slovenes.**—K. (Commander): **King of the Serbs, Croats and Slovenes.**—K. (Chevalier): **King of the Serbs, Croats and Slovenes.**—K. (3rd Class):

Brevet Lieut.-Colonel John A. Anderson, A.M.S.

DEATHS IN THE SERVICES.

COLONEL WILLIAM YOUNG, Bengal Medical Service, died at Northbank, Perth, on September 20th, aged 51. He was the younger son of the late Captain James Murray Young, of Hillhead, Glasgow, and was educated at Glasgow University, where he graduated M.B. and C.M. in 1892; he became F.R.C.S. Edin. in 1917. He entered the I.M.S. as surgeon lieutenant on January 30th, 1893, became lieutenant-colonel after twenty years' service, and attained the rank of colonel on March 23th, 1921. Most of his service was spent in civil employ in the United Provinces of Agra and Oudh (formerly the North-West Provinces), where he held for many years the important post of civil surgeon of Cawnpore. On promotion to the administrative grade last year he was appointed inspector-general of civil hospitals in the Central Provinces.

Medical News.

THE first meeting of the 150th session of the Medical Society of London will take place on Monday, October 16th, at 8.30 p.m., when the incoming president, Lord Dawson of Penn, G.C.V.O., will deliver his presidential address on "Certain developments in medicine," which will be followed by a discussion.

THE Museum demonstrations at the Royal College of Surgeons of England will be resumed on Friday next, October 13th, when Sir Arthur Keith, F.R.S., will exhibit specimens illustrating the effects of castration in man, at 5 p.m. On the following Monday, October 16th, at the same hour, Professor Shattoek, F.R.S., will demonstrate specimens illustrating the anatomical results of inflammation. Other demonstrations will be given on each Friday and Monday during October.

ALDERMAN J. T. T. RAMSAY has been elected mayor-designate of Blackburn. Dr. Ramsay is the first medical man to attain to mayoral rank in Blackburn, an honour which he has gained by a long and distinguished career devoted to the public service. He is a Scotsman, and received his medical education at the Edinburgh medical school, where he took the diplomas of L.R.C.P. and L.R.C.S. Edin. in 1891. He has been in general practice at Blackburn for the past thirty years.

THE annual dinner of the Society of Medical Officers of Health will be held at the Hotel Cecil, Strand, W.C., on Friday, October 20th, at 7.30 p.m. Amongst those who have accepted invitations are the Minister of Health (Sir Alfred Mould), Sir Arthur Robinson, Sir George Newman, Sir Humphry Rolleston, F.R.C.P., and Sir Anthony Bowlby, F.R.C.S. Ladies are invited, and members, or candidates nominated for election, are asked to give early notice to the Executive Secretary, 1, Upper Montague Street, Russell Square, W.C.1, of their intention to be present, with the names of their guests. A payment of 12s. 6d. for each ticket should be made with applications sent before October 14th; after that date the cost of tickets will be 15s. each.

A MEETING of the Metropolitan and Home Counties Sub-group of the Maternity and Child Welfare Group of the Society of Medical Officers of Health will be held at 1, Upper Montague Street, Russell Square, W.C.1, on Tuesday, October 10th, at 5.15 p.m., when a paper will be read by Mr. G. E. Wagh (senior surgeon to Great Ormond Street Children's Hospital) on "The prevention and treatment of nasal and aurial infections in infancy." Tea at 5 p.m. Members are invited to bring friends.

THE eleventh annual general meeting and conference of the British Commercial Gas Association will be held in the Museum and Art Gallery, Bristol, on October 16th, 17th, and 18th, under the presidency of Sir George E. Davies. Members of the conference will be welcomed at a reception on the evening of October 16th, when Sir Henry Garvain, M.D., will deliver a lecture upon "Light and life."

THE new post-graduate course at the National Hospital for the Paralysed and Epileptic, Queen Square, W.C.1, will commence on October 9th and continue until December 6th. The course will consist of lectures on the pathology of the nervous system, out-patient clinics, lectures and demonstrations on neurological ophthalmology, and clinical lectures and demonstrations.

UNIVERSITY COLLEGE, London, announces a large number of lectures; among others, a public lecture on "The beginnings of science," which Professor G. Elliot Smith, F.R.S., will give next Monday at 5 p.m.

The Life of Lord Moulton, by his son, the Hon. H. Fletcher Moulton, which will be published shortly by Messrs. Nisbet, should prove of special interest to medical readers. Medicine owes much to him as an exponent of its development, and for his memorable defence of the rights of research, while as chairman of the Medical Research Committee he did invaluable work.

DR. ROBERT KNOX will give a lecture on α rays and radium in the lecture theatre of the Medical School, King's College Hospital, Denmark Hill, to-day (Saturday), October 7th, at 4 p.m.

THE annual dinner of the London School of Tropical Medicine will be held at the Trocadero Restaurant on Wednesday, November 1st, at 7.30 p.m., with Dr. Hugh S. Stannus in the chair.

THE annual dinner of the Reunion Association in connexion with the Prince of Wales's General Hospital and North-East London Post-Graduate College will be held at Pagani's Restaurant, Great Portland Street, W., on Thursday, November 9th, at 8 o'clock, with Dr. F. G. Crookshank in the chair. The price of tickets will be 12s. 6d. each (exclusive of wines). Prospective members of this association are asked to communicate with the Honorary Treasurer, Mr. S. O. Rashbrook, 1, Priory Terrace, Kew, Surrey.

THE opening post-graduate lecture of the winter session will be given by Sir James Galloway, K.B.E., C.B., in the West Lecture Hall, Royal Society of Medicine (by kind permission), 1, Wimpole Street, W.1, on Wednesday, October 11th, at 5 p.m. The subject of the lecture will be "Hodgkin's disease and similar unexplained maladies" (with lantern illustrations), and the chair will be taken by Sir George Makins, G.C.M.G., C.B. The lecture is open to members of the profession.

THE Royal Sanitary Institute will hold a sessional meeting at the City Hall, Cardiff, on October 13th and 14th, when Dr. J. S. Peebles, M.O.H. Bridgend Urban District Council, will open a discussion on health education of children. A discussion on open-air schools will be opened by Mr. E. E. Morgan, borough architect, Swansea. The chair will be taken by Dr. Louis Parkes, chairman of the council of the Institute, at 4.30 p.m.

"HEALTH WEEK," which was instituted by the Royal Sanitary Institute in 1912, will be held this year from October 8th to 14th. Its object is to focus public attention on questions concerning public health, to arouse a sense of personal responsibility in it, and to create general interest in this work. The promoters of the movement hope that medical officers of health will make some special effort during the week to arouse public opinion in favour of a high health standard in each locality, and it is also suggested that school teachers might give simple health talks to school children.

THE autumn session of the West London Hospital Post-graduate College will open on Monday, October 9th, and will extend to Saturday, December 16th. There will be a lecture or demonstration at 4.30 p.m. every day except Saturdays; demonstrations will be given daily in the medical and surgical out-patient rooms and the special departments at 2 p.m.; and several courses of special lectures and demonstrations have been arranged. Full particulars may be had from the dean of the college, Dr. Arthur Saunders, at the West London Hospital, Hammersmith, W.6.

THE Herefordshire Medical Society has just acquired new quarters at 20, East Street, Hereford, which are open to any member of the profession who may be visiting the neighbourhood, as well as to subscribing members residing in the county. It is a very old society, and its members would be very grateful if any authors or others would contribute any modern books to augment the library. Communications may be addressed to Dr. J. Oswald Lane, Honorary Librarian.

THE late Mr. Daniel Clark of Cheltenham, who died on June 30th leaving net personalty of £43,786, has bequeathed £5,000 each to the Leeds General Infirmary and the Cheltenham General Hospital and £2,000 to the Bath Hospital, Harrogate. After paying other bequests the residue of the property, which will probably exceed £30,000, is to be divided between the following hospitals: St. Bartholomew's, Gny's, London, St. Thomas's, St. George's, King's College, University College, Charing Cross, St. Mary's, and Middlesex.

A GOLD medal and other gifts were presented to Professor Barduzzi at Siena recently, on his resignation from the chair of skin diseases and syphilis; the occasion was also the fiftieth anniversary of his professorial career. A history of his career was published and presented to him by the medical students.

MESSRS. BAILLIÈRE, TINDALL, AND COX announce for immediate publication a biography of Lawson Tait by Dr. W. J. Stewart McKay; a *Textbook of Industrial Hygiene*, by Dr. E. W. Hope, M.O.H. Liverpool; a fourth edition of Dr. Tredgold's *Mental Deficiency*; and the eleventh edition of Sir William Whitla's *Pharmacy, Materia Medica, and Therapeutics*. They also announce books by Drs. Pearson and Mosehet on the *Hygiene of Native Compounds in Tropical Africa* and by Harold Barrows, F.R.C.S., *Accidents of Surgery*.

DR. ROBERT TIDBURY, on the occasion of his retiring from the office of assistant medical officer of the Borough Mental Hospital, Ipswich, has been presented with an inscribed silver cup by the staff and a smoker's cabinet by the patients.

THE endowment received by Harvard University last year from the Rockefeller Foundation to establish a new School of Public Health has enabled the existing facilities for training and research in industrial medicine to be broadened and extended. The chief need of students is for brief courses, or groups of courses, of study and research leading to higher degrees. Students who enter for courses leading to a degree or for brief periods of special work must register in the School of Public Health, after satisfying the Committee of Admission of their fitness to pursue an approved course looking towards a definite objective. While the desirability of admitting students to short and highly specialized courses of study and practice is recognized, such opportunities are reserved for those whose academic or field training is recent and promises success in the programme outlined. To such special students no degree is given—merely a statement of the work done and the grades attained. The degrees offered in the School of Public Health are: Bachelor of Public Health; Master of Public Health; Doctor of Philosophy (in Hygiene); Doctor of Medical Sciences; Doctor of Public Health. Two years' study are ordinarily required of a medical practitioner aiming at the Doctorate in Public Health; during the first year he pursues courses bearing upon industrial hygiene; the second year is devoted to work in his special field, and to the composition of a thesis. Several fellowships of 1,200 dollars a year are open to those qualified to undertake work in any of the medical sciences bearing upon public health, in vital statistics, or in practical hygiene. Further information may be obtained from the secretary of the Harvard School of Public Health, Boston, Massachusetts, U.S.A.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecura*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus*, Dublin); telephone, 4737, Dublin, and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh); telephone, 4361, Central.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

QUERIES AND ANSWERS.

CORNS AND WARTS.

"C."—So-called corns on the soles of the feet often prove to be concealed warts and require surgical measures. The advice of a dermatologist could be sought, or, if the "corns" are associated with Morton's disease, it may be well to consult an authority on orthopaedic surgery.

MAJOR F. R. BORDEN, Medical Corps, U.S.A., writes from Camp Stanley, Texas, in reply to an inquiry published in our issue of August 5th (p. 240), that a simple and efficient remedy for warts of the scalp will be found in the daily application, for four or five days, of solution of formaldehyde, U.S.P., which appears to be identical with the solution of the *British Pharmacopoeia*.

INOCULATION FOR THE TROPICS.

"S. C." asks what inoculation, in addition to revaccination, should be given to a patient who is going out to a remote rubber plantation in the Straits Settlements.

* * * The patient ought to be inoculated with the triple typhoid vaccine—typhoid, paratyphoid A, and paratyphoid B. Two inoculations are required, and the material can be obtained from Burroughs, Wellcome and Co. Full directions are issued with the vaccine.

INCOME TAX.

"W." does part-time work for a county authority and is allowed a sum for travelling expenses by the authority.

* * * If he makes a general income tax return in one sum, including his county receipts, and deducting all his professional expenses, the amount allowed him should be included as a professional receipt; if, however, he returns the salary separately and deducts nothing, either in that return or in the return of his profits, on account of the travelling expenses which he incurs in connexion with his appointment, then the county allowance can properly be omitted from his receipts.

ASTHMA.

DR. ALEX. M. BREMNER (Wood Green, N.) writes in reply to Dr. Thomas Martin (September 23rd, p. 552): "I would suggest that he try calcii acetyl sal., gr. x, three or four times a day. I have used it for the last ten months with benefit in asthmatic cases, in some cases with very marked success. In children I use calcii lactate with benefit. As calcium salts are used to prevent amphyphaxis in using vaccines and antitoxins it seemed to me that they would be useful in asthmatic cases, as they are in urticaria. I have tried parathyroid tablets but got no results from them of any value."

CHAULMOOGRA OIL IN TUBERCULOSIS.

MAJOR V. T. CARAULTIERS, F.R.C.S. (Derby), writes: Can any of your readers refer me to any account of the use of chaulmoogra oil or its derivatives in tuberculosis? The similarity of the bacilli of leprosy and tuberculosis would lead one to expect good results from treating tuberculosis with the remedy so useful in leprosy; and the experiment has doubtless been frequently tried.

LETTERS, NOTES, ETC.

PREVENTION OF BOTULISM.

DR. GEORGE WILLETT (Keynsham, Somerset) writes: I would like to ask whether it would not be possible to introduce into the sealed tin of preserved food a small quantity of some material such as oxygen, or some oxygen-producing substance, with the idea of preventing the growth of the microbe *Bacillus botulinus*. It seems to me that this could be quite easily accomplished and foods so treated thus rendered harmless.

RASH FOLLOWING HYPOPHOSPHATES.

"J. A. MACM." writes: Recently I saw a patient with slight swelling of the thyroid gland on the left side, apparently an adenomatous condition. I prescribed compound syrup of the hypophosphates (5ss); after the first dose an urticarial rash, accompanied by intense itching, appeared; as she had been eating raspberries, I thought the rash was due to these and not to the medicine. However, I stopped it. The rash was followed by profuse desquamation. On August 7th she took another dose and again a similar urticarial rash with the itching appeared. I should be glad to know if hypophosphates are liable to do this. I have never seen a similar result before in twenty-five years' experience.

A SANITARY SEAT COVER.

A USEFUL and cleanly device, worthy of the attention of public health authorities and others, is the "White Star" sanitary seat cover, which is manufactured by Messrs. Vickers-Massey, Ltd., Sentinel House, Southampton Row, London, W.C. It consists of a wooden case with a hinged flap, containing sheets of thin paper which are drawn forward, as required, to cover the seat of a water-closet.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 30, 31, 34, 35, and 36 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 32 and 33.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 139.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£ s. d.
... ..	0 9 0
... ..	0 1 6
... ..	7 10 0
... ..	3 15 0
Half single column	10 0 0
Half page	20 0 0
Whole page	20 0 0

An average line contains six words

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be

to receive costs

MEDICINE.

247. The Nomenclature of Minor Mental Disorders.

MILLAIS CULPIN (*Journ. of Neur. and Psychopath.*, August, 1922, p. 105) criticizes the prevalent laxity in the use of the terms "neurosis" and "neurasthenia." After quoting the definition of "neurosis" in the *Oxford English Dictionary*, he shows that the word has been employed by distinguished writers in the eighteenth and nineteenth centuries to describe definite organic disease, and as late as 1874 Maudsley refers to insanity and epilepsy as "neuroses." Culpin claims that, speaking generally, functional nervous disorders are mental disorders. "Our own meaningless use of words with meanings has taught our patients to speak of their nerves with the same satisfaction with which our ancestors talked of 'rheums' and 'humours.'" He observes that "the source of greatest offence to accuracy of thought is 'neurasthenia.'" It has now become only a thought-saving device, and covers any disturbance of mental processes that is not insanity or a glaring hysteria." It connotes a pathology vague and indeterminate but influential. He agrees with Rows that we should cease trying to classify certain cases as epilepsy or hysteria and be content to describe them as "convulsive seizures." We must avoid diagnostic words that give a false sense of knowledge. Culpin proposes to limit the term "neurosis" to such a derangement of the intrinsic function of nerve tissue as is exemplified by D.A.H. "Psychosis" is usually applied to insanity, but some authorities have used it to denote minor disturbances—for example, H. Head uses "functional psychosis" as an alternative to "shell shock." Culpin suggests that the term "minor psychoses" may be used to indicate "functional nervous disorders," and under the heading "Conditions found in the minor psychoses" the author groups: (1) hysteria, (2) anxiety states, (3) obsessional states, (4) hypochondria, (5) psychasthenia, with (6) neurasthenia, which latter he and Ernest Jones have found actually present in only 1 per cent. of a series of cases. Such a word as "neurasthenia" is as powerful as it is pernicious—such phrases have been a real hindrance to treatment. By using words implying a pathology which may be, and probably is, false we hinder a healthy confession of ignorance or an acknowledgement of the difficulty of the subject.

248. Etiology of Whooping-cough.

T. P. HALL (*New York Med. Journ. and Med. Record*, August 2nd, 1922, p. 158), considering that the chief source of danger in whooping-cough is the associated stomach disturbance, found that considerable benefit resulted from stomach lavage. In eight cases immediate relief of symptoms followed, and the disease was cured in from three to six days, the spasms losing their intensity after the first day's lavage. The stomach washings contained a white tenacious mucoid mass consisting of thin-walled semi-mucilaginous threads 2 to 4 μ in diameter, each divided into cells 10 to 50 μ long, with some spore-like bodies of the same diameter. Growth in various nutrient media developed aerial spores, at first white and gradually becoming blue-green, producing a blue-green penicillium mould. A easily digested diet, excluding milk, should be given, and lavage undertaken twice a day before meals, two quarts of water at 100° F. being used containing alternately 20 minims of lysol and 3 or 4 drachms of sodium bicarbonate. In six cases with hoarse spasmodic cough, but without whoop, penicillium was present, and cure followed lavage in one to three days. In one other case no penicillium was found, and in another, which did not respond to treatment, a variety of penicillium was present in which the spores and threads were one-quarter the diameter of those found in the other six. The distress caused by the treatment is less than that from the cough, and becomes negligible after the third treatment.

249. Acute and Subacute Atrophy of the Liver.

F. UMBER (*Klinische Wochenschrift*, August 5th, 1922, p. 1595) draws attention to the increase of liver diseases, and of acute atrophy of the liver, especially in his own hospital practice in Berlin since 1919. Others have recorded similar experiences. The important pathological change in acute and subacute atrophy is the breaking down of the liver cells. The author considers that an important factor in the production of these changes is the deficiency of the glycogen in the liver cells owing to malnutrition; and as a result thereof the liver cells

cannot withstand the action of various bacterial and chemical toxic substances. The recent food deficiency in Germany has affected the liver especially; and the *post-mortem* observations of O. Weber have shown that in 1916-18 the weight of the liver was distinctly less than in 1914-15, whilst the weights of the heart, lungs, kidneys, and brain were unchanged. The question of the injurious action of salvarsan has been much discussed. Undoubtedly a liver injured by syphilis may pass into acute atrophy through the action of salvarsan. But the author thinks the injurious effect of salvarsan has been much overestimated. It has not yet been shown that in therapeutic doses salvarsan alone, without syphilis, can produce acute atrophy of the liver. Of the author's 33 cases 20 were females. The disease was not associated with phosphorus poisoning or with pregnancy in any of these cases. The most important symptoms are progressive diminution in the size of the liver (detected by palpation and percussion), which, at first enlarged, may finally disappear under the costal margin; signs of hepatic intoxication—increasing somnolence passing into deep coma, various irritative nervous symptoms in some cases preceding the coma; a peculiar, sweet, aromatic, characteristic smell of the breath; jaundice, and bilirubin in the urine (in all of the author's 33 cases). Ascites was only detected in 5 of the cases. The presence of leucin alone in the urine is of no diagnostic value; but the association of tyrosin with leucin is a characteristic symptom (11 in 33 cases). The temperature may be normal during the whole course, but sometimes rises rapidly just before death.

250. Ultra-violet Radiation in Rickets.

B. KRAMER, H. CASPARIS, and J. HÖWLAND (*Amer. Journ. Dis. of Children*, July, 1922, p. 20) give the results of treatment of five children showing clinical and x-ray evidences of rickets by systematic exposure to the rays from the mercury-vapour quartz lamp, healing of the process in the bones taking place in each instance. The effect of the ultra-violet radiation on the calcium and inorganic phosphorus concentration of the serum of these children showed a gradual increase of the latter, with the appearance of calcium deposit in the bones. Healing of the bones after radiation appears to occur at about the same time as it does after the administration of cod-liver oil, and the changes in the phosphorus concentration of the serum were identical with those following cod-liver oil treatment. The five children—four coloured and one white—were exposed to radiation from a mercury-vapour quartz lamp at a distance of 50 cm. every day for five minutes, gradually increasing to twenty minutes, 8 ampères of current being used. The ventral and dorsal aspects of the body were radiated on alternate days, the eyes being carefully protected. Before and during treatment frequent x-ray examinations were made, the calcium and inorganic phosphorus of the serum being determined at least once before and twice during treatment. The pigmented skin of the coloured children did not interfere with the action of the rays, and they required no more intensive treatment to produce healing than the white children.

251. Causation of Lathyrism.

H. W. ACTON (*Indian Med. Gazette*, July, 1922, p. 241) investigated the causation of lathyrism, a type of spastic paraplegia, occurring among the inhabitants of North Rewah, and generally attributed to an exclusive diet of kesari dāl (*Lathyrus sativus*). In some parts of Central India and the United Provinces about 6 per cent. of the population are affected, equivalent to 60,000 cases in North Rewah, the majority occurring between the 15th and 30th years, males suffering about eight times as frequently as females, and all of the lowest labouring classes. The great predisposing cause is the harwar system or system of bondage, and there appears to be a definite relation to famine years, and at such times the harwars (ploughmen) are paid in kind with the cheapest food (kesari dāl). The majority of cases occur in July, owing probably to the production of poisonous amines during germination, and, though an alkaloid has been isolated, the matter is still under investigation. The incidence of the disease is frequently associated with chills. Sudden in onset, without pain, the legs are noticed to be weak, and that there is difficulty in sitting down or getting up. In the earliest stage the patient can walk unaided, or with only a short stick, and has a characteristic hesitating springy gait on tiptoe. In the second stage he requires the support of a long stick, and the body is thrown forward with the knees more flexed and the foot slightly turned in, one foot being brought in front of the other owing to adductor spasm.

In the third stage two long sticks are used, the knees are acutely flexed and drawn one in front of the other (scissors progression). In the last stage the knees are flexed almost on to the thighs, and progression is only possible by crawling or by using wooden shoes for the hands. Consciousness is never lost, the bladder and rectum are not involved, Romberg's sign is absent, the knee-jerks are increased, ankle clonus is well marked, and Babinski's reflex is present. There is no paralysis, but the spastic condition involves the quadriceps extensors, adductors, gastrocnemii, and posterior peroneals, the trunk and upper limb muscles being unaffected. The condition is due to an upper neuronal lesion below the second lumbar root, involving the motor tracts, and apparently caused by an amine from the germinating seed of *Kesari dal*. Soaking the grain for twenty-four hours in three changes of water removes the poison. Prevention of the disease should be aimed at by abolishing the barwar system, by improving the agricultural methods, and instituting famine relief to decrease the consumption of *Kesari dal*, and by increasing the popular knowledge as to its toxicity and method of removal. The small-grained *Kesari*, being less toxic, should be grown to meet local requirements, and germination prevented by storing in dry places during the damp months of July and August.

252. Treatment of Diphtheria.

H. C. DRURY (*Irish Journ. of Med. Science*, June, 1922, p. 153), from considerable experience in the treatment of diphtheria by antitoxin, advocates a much smaller dosage than that usually adopted, his practice being in a mild case, either adult or child, to administer 2,000 units daily until the membrane disappears, with three doses at most. In severe cases required, while in desperate cases a dosage of 6,000 units should be given. By such a method toxæmia is suppressed and neutralized, the patients making a rapid recovery and becoming free from infection in a comparatively short time. Notes of two severe cases are given in which recovery took place after a total of 16,000 and 12,000 units respectively in divided doses spread over three days. It was found that such doses were quite as effective as larger ones in shortening the period of infection, and in the opinion of those having experience of both methods no better results are obtained by the larger doses. An experience of over eight years in treating bad scarlet fever throats by the administration of diphtheria antitoxin has shown the efficacy of such treatment on non-diphtheritic conditions, and the excellent results, originally accidentally discovered, have led to its adoption in severe scarlatinal sore throat with satisfactory results.

253. Treatment of Influenza.

D. SIMICI (*Paris méd.*, June 3rd, 1922, p. 474), owing to the difficulty of treating influenza by the injection of convalescents' serum, especially when a large number of patients have to be injected at once, has substituted the use of whole blood. Another advantage claimed by him for his method is that the albumin contained in the other elements of the blood apart from the serum are introduced into the organism as well as the bactericidal or antitoxic substances contained in the serum. The technique consists in injecting subcutaneously or intramuscularly 10 to 20 c.cm., which has been withdrawn a few moments before from a patient convalescent from a severe attack of influenza in whom the temperature has been normal four or five days. To prevent coagulation 2 c.cm. of a 2 per cent. solution of sodium citrate should first be drawn into the syringe and well mixed with the blood. Simici has employed this treatment in twenty-four cases of the septicæmic form of influenza, all of which were complicated by more or less extensive lesions of the respiratory system. Twenty recovered and four died. The effect of the treatment was indicated by the favourable action of the injections on the temperature, general condition, and respiratory symptoms, and also by an increased diuresis, patients who had previously been passing little urine excreting from 1,000 to 2,000 c.cm. in the twenty-four hours.

254. Treatment of Sycoosis.

MADERNA (*Rif. Med.*, July 3rd, 1922, p. 625) reports 11 cases of tinea sycoosis successfully treated by means of endovenous injections of Lugol's fluid. This is made up of iodine 1 gram, potassium iodide 2 grams, and distilled water 300 grams. The initial dose is 1 c.cm. diluted in 10 c.cm. of water. An injection was given every other day, increasing the dose to 5 c.cm. If the case was seen early—for instance, within five to ten days—cure was usually obtained in fifteen to eighteen days after seven or eight injections; if later, twelve to fourteen injections were required. No ill effects were observed, and the results were equally good with the sycoitic as with the erythematous squamous type of trichophyton infection. Illustrations before and after treatment are given.

SURGERY.

255. Torsion of the Spermatic Cord in Children.

ALBERT MOUCHET (*Paris méd.*, July 15th, 1922, p. 63) describes two cases which illustrate the two types of this condition: (1) volvulus of testicle in an abnormally large tunica vaginalis and (2) true torsion *en masse* of the spermatic cord above the tunica vaginalis. Case I.—A boy, aged 8, whose parents had observed for three months that the left side of his scrotum had enlarged to the size of a pear. Three days before admission he was seized with violent pain in the left testicle, accompanied by vomiting. On admission, the pain was less severe, and, except for a slight rise of temperature, there was little systemic disturbance. The right side of the scrotum was normal, but the left was swollen to the size of a small lemon and was too painful to permit the testicle and epididymis to be felt. The skin was red and the subcutaneous tissues oedematous; the swelling was translucent. The cord was intact and the urethra healthy. A provisional diagnosis of inheerulous epididymitis was made. Local treatment gave some relief, and two days after the onset an exploratory puncture yielded a small quantity of lemon-coloured fluid containing red corpuscles and polymorphs. The pain persisting, two days afterwards the tunica vaginalis was opened (under a general anaesthetic); it contained about 12 c.cm. of yellow serum; the testicle was normal, but the gloins major was swollen to three times its size and the whole epididymis was separated from the testicle. The cord was swollen and was twisted spirally three times from left to right inside the tunica. It was easily reduced, the epididymis fixed to the upper surface of the testicle, and the tunica vaginalis resected. The testis was only slightly congested, and the patient made a rapid recovery. Case II.—A boy of 9 was admitted with a large swelling of the left side of the scrotum, attributed to a fall on one of his sabots. He felt a sudden pain, which quickly disappeared, and nothing further occurred until he was awakened in the night by severe scrotal pain and vomiting. Pain and malaise persisted for three days, when he walked to the hospital. The symptoms resembled those of Case I; the cord was intact, and there was no urethral discharge. There were no ecchymoses nor history of infection. Seven days after the onset the oedematous scrotum was incised; on opening the tunica vaginalis the testis was seen to be quite black. A second incision near the external ring showed that the whole cord had been twisted one and a half turns from left to right. As the testis appeared to be gangrenous it was removed. Pathological investigation showed that it was quite disorganized.

256. The Cause of Fatalities from Intraspinal Anaesthesia.

S. WIDERÖE and S. DAHLSTRÖM (*Norsk Mag. for Lægevidenskaben*, June, 1922, p. 450) note that the intraspinal injection of novocain or stovalno not infrequently causes paralysis of respiration, necessitating prolonged artificial respiration. Investigating the mechanism of this accident, they have experimented on syphilitic lunatics, injecting air and phenol-sulphonaphthalein into the spinal canal, and noting the time taken for the air and the dye to reach the ventricles of the brain. When the dye was injected into the ventricles of the brain it was almost at once found in the cerebro-spinal fluid, and when the dye was injected into the spinal canal it was found within five minutes in the ventricles of the brain. Intraspinal injections of air also showed that it could easily escape to the surface of the brain and into its ventricles. The authors conclude that respiratory failure following the intraspinal injection of an anæsthetic is probably due to the action of the anæsthetic on the fourth ventricle.

257. Early Stages of Acute Pancreatic Necrosis.

H. ZOEPFEL (*Klinische Wochenschrift*, June 10th, 1922, p. 1203) points out that acute pancreatitis is one of the rarer complications of gall-stone affections (10 cases met with amongst 150 operations on the biliary passages; in 9 of these cases direct connexion with gall stones, in one case connexion probable). When a gall stone obstructs the terminal common portion of the ducts from the liver and pancreas the obstructed bile is pressed into the pancreas and acute pancreatic necrosis may follow. But other cases are met with in which operation reveals oedema of the pancreas and adjacent parts without necrosis. Three such cases are recorded, and the author regards the condition as an early stage of pancreatic necrosis. In all three cases there was a previous history of gall-stone attacks, then a specially severe attack with desperate pain in the epigastrium; in all these cases gall stones were found. Operation was performed within the first twenty-four hours, and all three patients recovered. Death occurred in seven cases operated upon after twenty-four hours,

and haemorrhagic necrosis was found in the pancreas. If, in the course of cholelithiasis, a specially severe attack occurs, with pain which radiates to the left in the epigastrium, with tension, or only tenderness on pressure in this region, the possibility of commencing acute pancreatic necrosis should be thought of, and operation immediately performed. The author thinks his observations indicate the value of early operation in certain gall-stone attacks, since early pancreatic oedema is thereby prevented from developing into actual pancreatic necrosis. Also in early operations generally, the gall stones may be found in the gall bladder, and their passage into the choledochus prevented, and thus the chief cause of pancreatic necrosis avoided.

256

Pulmonary Decortication.

ROUX-BERGER (*Bull. et Mém. Soc. Chir. de Paris*, May 9th, 1922), in discussing the treatment of pleural empyema, finds that the best position for operation is for the patient to be seated. It has the advantage that the patient is in the same posture as that in which he was x-rayed, and respiration is rendered easier. He then describes the operation of pulmonary decortication—here, a general anaesthetic is necessary and the prone position is found best. Before this operation is carried out it is advisable to investigate the type of organism present and the size of the cavity in the chest. The most difficult cases are those occupying the whole extent of the thorax, reaching from the first rib to the diaphragm; in these cases pulmonary decortication is necessary. When the whole lung is involved the operation cannot be completed through a single incision. In certain cases it is essential to reach the apex of the lung. The lung always retracts away from the chest wall, whilst the base and the apex remain in position, and usually have firm attachments which limit the retraction to some extent. In some cases the apex retracts downwards, but he has never seen the base separated from the diaphragm. If decortication is incompletely carried out a firm cap is left over the summit of the lung which prevents its ultimate expansion. With a low incision one cannot reach the apex of the lung satisfactorily, and a second incision over the second intercostal space may be required. Such an operation may be carried out in two stages. In those cases where only a small cavity is found, occupying three or four spaces, the treatment is relatively simple compared to the above—the fistula then being opened up and the cavity itself treated.

259.

Rare Localizations of Hydatid Disease.

L. BACCARINI (*Il Policlinico, Sez. Prat.*, May 22nd, 1922, p. 676), who records a case of echinococcus cyst of the neck in a boy aged 10, successfully removed by operation, states that little attention has been given to this localization of hydatid disease. Of 116 cases of hydatid disease studied in the Paediatric Clinic at Montevideo by Morgno and De Penna, only three occurred in the neck. As a rule, a hydatid cyst in this region is situated below the sterno-mastoid along the course of the large vessels. It is very unusual for it to be situated in the posterior part of the neck, as in the present case, and rarest of all to be within the substance of the sterno-mastoid. When it has attained a certain size, the cyst may give rise to symptoms of compression on the vessels, more rarely on the nerves, and disturbance of deglutition, phonation, and respiration. As a rule, a hydatid in the cervical region develops fairly slowly, at some periods remaining almost stationary, and at others taking on a rapid growth. Cervical cysts are generally single and do not contain daughter cysts. The only certain method of diagnosis is exploratory puncture, which reveals the presence of characteristic hooklets. ROMANO (*ibid.*, p. 678) records a case in which the hydatid cyst was situated either in the omentum corresponding to the greater curvature of the stomach or in the retroperitoneal connective tissue of the left hypochondriac region. Its exact position could not be determined, as the patient refused operation.

260.

Sciatic Hernia.

J. E. SUMMERS (*Annals of Surgery*, June 1st, 1922, p. 672) points out that this type of hernia may be met with in three forms—those which pass out both posterior sciatic notches, the greater sciatic notch, and the lesser sciatic notch. In all cases the hernia will have the greater sacro-sciatic ligament under it. The hernia then appears in the gluteal fold under the gluteus maximus. There is a greater frequency for this hernia in the female sex, probably because the notch is slightly larger and the ligament in women is of greater length and laxity. The hernia occurs more commonly on the right side. It is most frequently caused in women as a result of the pressure and trauma of labour, and may contain any viscous sufficiently inovable to pass out of the pelvic cavity. The hernia varies in size from a chicken's egg to a grape fruit, and may be mistaken for a teratoma or lipoma. Unless

symptoms of strangulation are produced it is best left alone. When interference is necessary an attempt should be made to close the hernial opening from without; in the presence of strangulation a combined operation should be performed. In operating a large incision through the gluteus maximus is made and the two flaps retracted; the sac is isolated and incised. If it is necessary to enlarge the hernial opening care must be taken not to injure neighbouring arteries. The contents and the sac are then dealt with in the usual manner. If gangrene has developed the operation must be completed by the abdominal route. The author refers to twenty-five cases reported in the literature, and describes a case of his own.

OBSTETRICS AND GYNAECOLOGY.**261. Anteversion and Retroversion of the Uterus.**

ONE thousand consecutive unmarried women, aged from 15 to 45 years, who had no record of pelvic infection, pelvic tumour, or pregnancy, were investigated by LEDA J. STACY (*Journ. Amer. Med. Assoc.*, September 2nd, 1922, p. 793) to determine, if possible, the relative frequency with which the various displacements of the uterus and the attendant symptoms occur in cases in which no pathological or physiological factors could have affected the position of the uterus. Retroversion of the uterus was found in 202 (20.2 per cent.). Anteversion, probably the normal position in most cases, occurred in 798 (79.8 per cent.). In view of the fact that the infantile type of uterus with which one expects to find delayed menstruation is more often in anteversion, it is of interest that in these cases menstruation was established at the average age of 13.85 years, and in cases of retroversion at the average age 14.18 years. Dysmenorrhoea occurred in 102 (12.8 per cent.) of the patients in whom the uterus was in anteversion, and in 33 (16.33 per cent.) of the patients with retroversion. Backache occurred during menstruation in only 7.25 per cent. of the 798 patients with anteversion, and in 11.38 per cent. of the 202 patients with retroversion. Inter-menstrual backache occurred in 8.39 per cent. of all the patients, although the ratio remained the same in retroversion and in anteversion. None of the 1,000 patients had marked leucorrhoea. Operation for pelvic complaints (practically always dysmenorrhoea) was advised for only 6 (0.75 per cent.) of the patients with anteversion, and for 3 (1.48 per cent.) of the patients with retroversion. There seems to be little difference in the character and incidence of symptoms as a whole in cases of anteversion and in cases of retroversion of the uterus. Congenital retroversion of the uterus, associated with backache, dysmenorrhoea, and so forth, usually is part of a general picture of deficiency of development. Surgical procedure to relieve pelvic symptoms in uncomplicated cases should be advised only after careful study of the patient from the point of view of the general, as well as the gynaecological, condition.

262.

Calcification and Torsion of Myomata.

ACCORDING TO F. MONTUORO (*Rivista d'Ostetricia e Ginecologia Pratica*, June, 1922, p. 300), calcification of uterine myomata is not rare, being found in 3 to 10 per cent. of cases. It may occur as a consequence of post-menopausal degeneration of the uterine vessels, or in some cases appears to have been brought about by reason of the occurrence either of torsion of the pedicle of a myoma or of axial rotation of a myomatous uterus as a whole. The case is recorded of a nullipara, aged 63, in whom a myoma had increased in size and become progressively harder after the menopause; at operation the calcified myomatous uterus was found to be axially rotated. Torsion facilitates calcification, but the reverse is also true, especially in the case of pedunculated tumours. Calcified myomata, besides causing intolerable pain, may lead to grave consequences by reason of their compression of the pelvic or other viscera; their removal is, as a rule, easy and well borne by the patients in spite of their advanced age.

263.

Regulation of the Placental Circulation.

W. SCHMITT (*Zentralbl. f. Gynäk.*, July 22nd, p. 1190) confirms the finding of other observers that nerve endings cannot be distinguished in the walls of the placental blood vessels nor in the umbilical cord; from anatomy, therefore, it appears probable that the vessels are regulated by other influence motor nerves. Testing the response of stimulation of the placental vessels, both in perfusion experiments and in strips of excised surviving arterial wall, he found that the vessels dilated in response to warmth, contracted after application of histamin, pituitary extract, or barium chloride, and dilated under the influence of amyl nitrite. In contrast to other blood vessels, however, which

contract in response to adrenalin in concentration so low as 1:11 in 20,000, the placental arteries showed little if any variation in the presence of concentrations of 5:1 in 1,000 of that substance. Since adrenalin acts on the nerve endings at myoneural junction, these experiments afford physiological evidence that the placental circulation is independent of nervous regulation. In both modes of experiment the blood vessels showed a remarkable sensitiveness to the oxygen tension to which they were subjected. Their tone was increased, in the presence of increasing amounts of oxygen, to a definitely proportional extent; and this reaction was absent in control experiments with the carotid artery of the ox. It is suggested that *in vivo* the calibre of the placental arteries is regulated by the oxygenation of the foetal blood; hypoxaemia leads to vaso-dilatation, and in the presence of high oxygen tensions the vessels contract.

264. Value of Oophorectomy.

S. ROTTENBERG and G. SCHWARTZ (New York Medical Journal and Medical Record, July 5th, 1922, p. 39), in cases in which an ovary appears unduly large or tense, or in which there are symptoms pointing to menorrhagia, metrorrhagia, or dysmenorrhoea of ovarian origin, have found it useful and safe to examine the interior of the ovary by splitting it in half from the free convex border to the clamped pedicle; catgut sutures restore the integrity of the ovary, of which the function is not subsequently impaired. They state that most ovarian cysts, especially teratomas, arise from embryonic rests in the medullary portion of the organ, and that primary ovarian cancer in its early stage is not recognizable from the exterior, the ovary, in spite of its enlargement, presenting a smooth surface. By splitting the ovary the early stages of morbid conditions, which might otherwise escape recognition, may therefore be detected. In two such cases, of which the histories are given, the writers found small dermoid cysts in the interior of not greatly enlarged ovaries in young patients.

PATHOLOGY.

265. Significance of Colostrum.

THEOBALD SMITH and RALPH LITTLE (Journ. Exper. Med., August, 1922, p. 181) have carried out a series of experiments to ascertain what is the function of colostrum to the newborn calf. Two sets of 10 newborn calves were kept as far as possible under identical conditions, and all of the 20 calves which were permitted to take colostrum after birth survived, whereas of the 10 calves which did not get colostrum 8 died and 1 was killed, moribund. Bacteriological examination revealed in nearly every fatal case a *B. coli* septicaemia, indicating that the calf deprived of colostrum lacks something which permits intestinal bacteria to invade the body and multiply in the various organs. In most cases where the calf is deprived of colostrum a rapidly fatal *B. coli* septicaemia develops; but should the animal survive for a few days, then fibrinous and purulent exudations are likely to appear in the joints and kidneys, these also being caused by *B. coli* or some organism associated with it. The cultural characters showed this strain of *B. coli* to belong to that variety which is non-motile, indol-producing, and which fails to ferment saccharose. It appears that the function of the colostrum is essentially protective against miscellaneous bacteria which are harmless later on when the protective functions of the calf have begun to operate and accumulate energy. There seems to be no function in colostrum which controls development or growth or which is essential to the starting of the mechanism of digestion, since calves not having had colostrum appear to do as well as the others when the infection has been overcome.

266. The Medico-Legal Significance of Intracranial Haemorrhages in the Newborn.

J. JÖRGENSEN (Ugeskrift for Læger, July 20th, 1922, p. 869) discusses the significance of intracranial haemorrhages in newborn infants. At one time this condition was interpreted as evidence, practically irrefutable, of violence done to the infant after birth; in a case published in Sweden in 1918 this was the chief evidence on which sentence of two months' imprisonment was pronounced on a woman. The author has investigated the records of 147 necropsies made on newborn infants for medico-legal reasons in Denmark in the period 1911-20, and he has found that large or small intracranial haemorrhages were found in 23 cases. Ten of these cases could be eliminated because there were other lesions indicative of violence inflicted after birth. Another case was not of interest in this question because the intracranial haemorrhage followed forceps delivery. After giving details of the remaining 12 cases, the author comes to the conclusion that this lesion may well occur during labour, and that this may

be either precipitate or quite normal. In other words, an intracranial haemorrhage is not necessarily indicative of prolonged and difficult labour. It is not, therefore, necessary to disbelieve the mother who states that she was surprised by labour, and that it was so precipitate that she had not time to summon help. The author also found that even a slight intracranial haemorrhage may be sufficient to cause death, for a slight haemorrhage may be the result of serious injury during labour.

267. Human Infections with *B. aertrycke*.

The troubled question as to the identity or the duality of the two micro-organisms—*B. paratyphosus* B, Schottmüller, and *B. aertrycke*—has been attacked once more by A. BESSON and Y. DE LAVERGNE (Ann. de l'Inst. Pasteur, June, 1922, p. 502). Actually their work has consisted in comparing four strains of *paratyphosus* B, isolated from the stools of patients suffering from gastro-enteritis, with six strains of *paratyphosus* B, recovered from the blood of patients subject to paratyphoid infection. Though resembling each other very closely, certain differences could be substantiated between them. Thus, the former group proved to be more resistant to malachite green, while their behaviour on media which had been previously exhausted with other organisms of the enteric group was distinct from that of the blood strains. By employing a strict paratyphoid B, Schottmüller, serum they showed that only the blood strains were affected, while, when a polyvalent paratyphoid B serum was used, both groups were agglutinated. Absorption tests, however, performed on this serum served to differentiate the strains fairly sharply. Finally, crossed immunity experiments on guinea-pigs revealed inequalities in the protective powers of the two groups towards each other. From these observations they conclude that the blood strains are identical with *B. paratyphosus* B, Schottmüller, and the faecal strains with *B. aertrycke*, while the differences substantiated between these two type strains are sufficient to warrant their being regarded as two definite species.

268. The Virus of Herpes and the Virus of Encephalitis.

In an article by C. KLING, H. DAVIDE, and F. LILJENQUIST (C. R. Soc. Biologie, June 10th, 1922, p. 79), certain data are advanced which militate against Levaditi's contention that the virus of herpes and the virus of encephalitis lethargica are identical. Exact microscopical studies of the lesions produced in the brains of rabbits after intracerebral inoculation with each virus has been carried out and the two sets carefully compared. In the case of the herpetic virus a definite meningitis is found; there is an infiltration with large numbers of cells, of which the majority are mononuclears, though polymorphs are quite frequent. In the brain the main lesion is found in the cortex; not only are foci of cellular infiltration seen, but there is a diffuse inflammation throughout the cerebral tissue; polymorphonuclear leucocytes are abundant, and are often collected into small groups forming miniature abscesses. In the case of the encephalitic virus, on the other hand, the meningeal infiltration is less marked and is more or less limited to the area around the vessels; the cells, too, are mainly lymphocytes, no polymorphonuclears being seen. In the brain the cortex is generally exempt; it is the mesencephalon which is attacked. Here there are definite foci of inflammation, perivascular cuffs of cells, and striking alterations in the nerve cells themselves. The authors consider that the lesions produced by these two viruses are sufficiently distinct to preclude—or, at any rate, to form a contraindication to—their identity.

269. Buccal Infection with the Tubercle Bacillus.

S. ROODHOUSE GLOYNE (Tubercle, August, 1922, p. 497) has attempted to answer the questions: (1) Are virulent tubercle bacilli commonly present in the mouths of patients suffering from pulmonary tuberculosis? (2) If so, can these organisms be transferred to table utensils? And (3) Does the washing of these utensils destroy the bacilli? Of 20 sputum-positive of these patients 10 had only a little and 10 had much sputum. Their mouths were washed out with 40 to 50 c.c.m. of sterile water containing 0.5 per cent. antiformin to destroy secondary organisms. The centrifugized deposit was injected into guinea-pigs, and of the 10 cases with scanty sputum 2 gave a positive result, and of the 10 with much sputum 8 gave a positive result. Similar experiments made with spoons used by 20 patients yielded 60 per cent. positive results in cases with profuse expectoration, whereas none of the 10 patients with scanty expectoration gave positive results. Other table utensils were not found to be infected, and samples of ward crockery also gave negative results. The author concludes that patients with profuse expectoration are more infective than those with scanty expectoration, and that plain water, used in sufficient quantities, is a satisfactory sterilizing agent in consumption hospitals.

NINETIETH ANNUAL MEETING
OF THE

British Medical Association.

Held at Glasgow, July, 1922.

PROCEEDINGS OF SECTIONS.

SECTION OF OBSTETRICS AND
GYNAECOLOGY.Professor EWEN J. MACLEAN, F.R.S.E., M.D., F.R.C.P.,
President.DISCUSSION ON
ANAESTHETICS AND ANALGESICS IN LABOUR.

OPENING PAPERS.

I.—W. OSBORNE GREENWOOD, M.D., B.S., F.R.S. EDIN.,
Harrogate.

It is only within the last few years that we have come to realize that labour, in 95 per cent. of cases, is not the normal physiological process of which our immediate forebears so glibly talked, but is one of the desperate fears and grey spots in the modern woman's life. It is only a humane platitude to say the sufferings in labour have as much claim upon our skill and sympathies as those of any disease. If, therefore, by our obstetric art we can "life's leaden metal into gold transmute," no further apology is needed. It may be objected that this is largely a sentimental view, but when we have come to the conclusion of the whole matter we shall see there are very decided and practical advantages on the physical and physiological sides. For upon our estimate and appreciation of the influence of pain and fear in parturition will depend our attitude towards the need for anaesthetics and analgesics in labour. In spite of Hilton's classic, *Rest and Pain*, little progress was made until recent years in our estimate of the real part pain plays in the pathology of our chief organs, even to the point of the *exitus lethalis*. But the work of Crile and a host of others has taught us how profound the effects of pain and fear may be upon such master

secondary attempt to dismiss them as we will, the fear and pain of labour are daily having their baneful effects on vital organs, and a studied indifference is not a specific against what may prove eventually to be permanent lesions in cerebral or suprarenal cortical cells. But the very choice of to-day's subject may be taken to show that we are convened to discuss seriously the real merits of some means of alleviating travail provided they are safe.

Without further preamble it may be said that the practical methods which hold the field at present are ether, chloroform, nitrous oxide, and scopolamine-morphine. Not that these represent the final word in the immediate future, but other methods already tried tentatively have not attained the certainty or the practicability of the above. I wish to state at the outset that it is my intention to regard the question of anaesthetics and analgesics largely from the viewpoint of shock, and this will explain what I say later. If chloroform or ether or nitrous oxide be administered at the end of a labour solely for the purpose of carrying out some operative procedure, such as extraction with forceps or a cephalic perforation, we cannot in any sense regard the anaesthetic as an essential part of the treatment—it is, so to speak, an accidental accessory. Such a use as this has its time-honoured place in labour. But it may be taken this discussion has a far larger end in view. Shock and exhaustion are in no degree whatever prevented by this accidental use, and we are here to determine as far as we can how the dangers of shock may best be averted by making anaesthesia or analgesia, or some modification of them, an essential part of the conduct of labour.

The recent work on shock and exhaustion has radically altered our conception of the part these two play. But though the limits of this paper forbid me examining these thoroughly it may be stated as well proven that the injury to cerebral, suprarenal, and hepatic cells is not only serious but often irreparable and fatal. Acidosis, oedema, rupture of the membrane, and

disintegration of the nucleus form the chain of changes in cells of the most vital organs. And while one would not be so foolish as to say this complete chain is common in labour, yet who can tell how many of the ill-defined ailments in a woman's middle life, for which no gross lesions can be discovered to account, are due to the destruction of a limited number of cells consequent upon labour? I think this is more probable than has so far been conceded. And when we reflect that the causes of shock are trauma and pain, emotion, especially fear, exertion, insomnia, haemorrhage, the infections and injection of acids, and that all these save the last two are operative, sometimes markedly so, in labour, it is evident we need a more systematic shielding during parturition if we are to give the pregnant woman not only the benefit of our knowledge and skill but an assurance that these are hers for the asking. The fear of labour harboured by women has been scoffed at and scouted, but after insisting for many years on its reality and importance it is gratifying to find such confirmation in Crile as this:

"Emotion causes a more rapid exhaustion than is caused by exertion, or by trauma, except extensive mangling of tissue, or by any toxic stimulus except the perforation of viscera" (p. 60).

And again:

"Fear caused profound changes in the cells of the brain, the liver, and the adrenals" (p. 63).

It must now be clear enough that, especially in the longer and severer labours, there is need for some protection of these vital tissues, and we are prepared for a comparison of the claims of the most suitable methods of attaining this. Of the general anaesthetics nitrous oxide is the best in the sense that it comes nearest to the ideal of a shockless operation. After prolonged administration the serious changes in the cells above enumerated are scarcely to be found, sometimes not at all; but against anything approaching its universal use are the grave disabilities of an almost prohibitively cumbersome apparatus, the cost, and a virtually continuous administration, maybe for many hours. I doubt whether any maternity hospital could bear the financial drain of using it for all cases, and certainly the vast army of the middle class could not. And while the actual cost of chloroform or ether is not prohibitive the other objections are very serious. If given *à la reine* a very skilled anaesthetist would usually be needed many hours, to requite whose services would naturally be very costly. The labour would be very greatly retarded, while *post-partum* haemorrhage is certainly more common and severe. Most serious of all, so far from preventing or even reducing shock, chloroform and ether are actually prone to initiate and continue those cell changes of acidosis, oedema, and even disintegration, which we are seeking to avert. Again quoting Crile:

"Prolonged inhalation anaesthesia caused acute blood acidosis, and the usual histological changes in brain, liver and suprarenals" (p. 73).

And also:

"The human mechanism in shock or exhaustion is not restored by physical injury, nor by strychnine, alcohol, anaesthetics, camphor oil, anxiety, painful examinations, rough handling, but by rest and sleep" (p. 185).

While, therefore, on the one hand, chloroform and ether, given at the end of a labour for some operative interference, do not supply the protection from shock which we seek, on the other hand, given *à la reine* for many hours, they actually intensify the ills. In addition to which, this latter method is infinitely more exacting to the attendant than the remaining method we are to consider. In fine, a prolonged general anaesthesia is now known to fulfil none of the demands of a "shockless operation." The ideal technique of this is not applicable to labour, since cocaine and its congeners are useless and the spinal method is little better. Crile's work abounds in quotations representing his own experiments and those of many others showing the remarkable results of the shockless operation methods, but very few must suffice.

"No amount of burning, cutting or crushing caused any notable change in the circulation or respiration provided the central nervous system had been previously disconnected from the injured area by the blocking of the nerve supply with a local anaesthetic" (p. 25). "Nerve trunks may be physiologically blocked by a local anaesthetic so that neither afferent nor efferent impulses of any kind can pass, hence no injury of an area thus protected can cause even the slightest degree of shock" (p. 34). "Of great significance is the fact that the brain

cells showed no change when the trauma was limited to the territories disconnected from the brain by severing the spinal cord or by local anaesthetization" (p. 41).

Now although scopolamine-morphine (or scop-omnupon) cannot be regarded as a local anaesthetic in the sense that cocaine is, my thesis is, it is sufficiently so in a far larger sense—namely, by cutting off the cerebral cortical cells from the remainder of the body—as to be the ideal method for use in labour, exactly as cocaine is for the performance, say, of a radical cure of hernia. We must remember that the traumatic area in labour is a very wide one, including not only a vastly enlarged uterus and its appendages, but pressure effects on bladder, large intestine, and perineum—the nerve supplies of which are from very diverse sources.

Crile has pointed out that insomnia produces shock, and the results on brain and other tissue cells are the same as trauma, only more gradual. Sleep is the great preventive of and restorer from shock, and Crile says:

"There is a vast clinical experience as well as supporting histological evidence that morphine as a substitute for sleep accomplishes for the brain cells much of what is accomplished by sleep" (p. 50).

And again:

"The cells of the brain, liver and adrenals are more restored by opium than by any other agency excepting sleep. Nitrous oxide to some extent effects a like restoration but is not as potent as opium" (p. 54).

We are now on the threshold of my contentions respecting the use of omnupon-scopolamine in labour in preference to any of the other methods outlined. For although the obliteration of the great bulk of the labour is the thing which appeals most to the patient and which was so boomed in the lay press, to the scientific obstetrician it is far more valuable to realize it is a shockless surgical operation. Not only so, an absolutely correct technique, so far from carrying any menace to the infant, confers the same advantages on it as are enjoyed by the mother. And this effect on the mother is not surprising when we reflect that the great bulk of the time occupied by the labour is spent in apparently normal sleep. The consideration of outstanding importance is brain-rest, and if we secure this while the essential labour organs—that is, uterus and abdominal muscles—perform their functions perfectly, we have not only secured an ideal labour but have also attained a shockless operation. The general anaesthetics fall short of this high standard.

In the light of the recent work on shock the suggestions I put forward five years ago as to the way in which scopolamine-morphine probably acts have become invested with a new interest. As is well known a local anaesthetic cuts off the area under manipulation from the rest of the nervous system. Especially does it prevent the cerebral cortical cells and the receptive white matter receiving painful afferent impressions. My thesis then was, and is now, that omnupon-scopolamine causes the retraction of the dendrites of the cells, and it is therefore at these synapses where the block occurs, and hence there can be no diffusion of stimuli. This, I admit, may equally well occur at a subcortical centre, but probably not in the cord. We know that this shrinking of dendrites, and therefore imperfection of synapsis, is common in old age, and it is then that memory for recent events may be very imperfect or even absent, while the memory of past events is usually quite accurate. The interesting feature is that the amnesia of this semi-narcosis is an exnet temporary induction of the forgetfulness of old age. Anent this, Crile's observation (p. 177) is peculiarly interesting:

"The synapse may be regarded as a highly adapted switch which now closes the circuit, now opens it; now diminishes the current, now accelerates it. This living switch or key may be the site of the activation of tetanus or strychnine convulsions. It may possibly determine sleep or the action of certain anaesthetics."

From this it would seem clear that in strychnine and tetanus poisoning there is no excitation of cerebral cells, but the synapses are closed and there is a continuous electrical discharge. This appears to be countenanced by the fact that complete consciousness is retained to the end. Sherrington's work also very strongly bears out this view. This theory accords perfectly with the fact that powerful stimuli applied during the sleep of the labour are afterwards remembered, for they jump the increased gap between the retracted dendrites just as an electric current of higher potential will spark across a wider gap than will one of lower potential.

The limitations of time compel me to pass now to a brief survey of the correct technique to be observed in successfully inducing this semi-narcosis, the effects on the mother and those on the infant. As usual, every case is regarded as a major surgical operation and the ordinary aseptic precautions rigidly observed. And first, we must decide how early the treatment may be begun. In primiparae it is very important to be sure the labour has really set in and the os has made some progress in dilatation. A fairly safe average guide is to begin when the os is the size of a shilling. In any case regularity of the uterine contractions must be established. In multiparae, however, the first injection may be given as soon as several good contractions have demonstrated the onset of the labour. From the moment of this decision the judgment of the attendant must be continually on the alert if he is anxious to obtain the best results. Thus it may be stated that for the majority of patients the first dose should be omnupon 1/3 grain (or morphine 1/5 grain) with scopolamine 1/150 grain. But even here not enough attention has been paid to the variation of the initial dose according to the type of patient. A small, worn-out, phlegmatic woman would not need quite as much as this, while a large, athletic, vivacious type may easily need half a grain of omnupon and scopolamine 1/120 grain. Having received the first injection the patient is bidden to lie down, be calm, and go to sleep with the confident assurance that the labour will proceed well. This, of course, presupposes that a previous examination has shown it to be reasonably anticipated, that any malpresentation has been rectified or can be during the progress of labour, and that any disparity in the size of pelvis and foetal head has been met by a suitably timed premature induction, etc. In from an hour to an hour and a half the patient should be sleeping comfortably between the uterine contractions, which will rouse her at each onset. Judged by the amount of sleep the patient has had, and to some extent by the flushing of the face, the second dose may vary between 1/150 and 1/450 grain of scopolamine alone, usually not so small as the latter. About half an hour after the second injection the testing for amnesia is begun. The majority of patients have not responded enough until this time and the testing is therefore an act of supererogation. This testing is the only certain way of determining success or failure in spite of repeated asseverations to the contrary, and the borderline between the two is so narrow that its importance cannot be overrated. Success means that the patient has reached the stage of forgetfulness—no more, no less. And it must be regarded equally as failure if the patient does not reach the amnesic condition or if she is needlessly beyond it. To aim at analgesia is not only unnecessary but oversteps the safety line. In every ideal case there is probably some analgesia; for which it would be better to reserve the term "hypalgesia." To adopt this would emphasize the fact that any marked analgesia is unsafe. From this point onwards there may be the greatest diversity in the dosage, and the amounts of scopolamine are determined entirely by the anesic state of the patient. So too are the intervals at which a repetition of scopolamine is necessary. It may be added that towards the end of the labour it is well to avoid if possible the administration of any dose too near the moment of expulsion of the infant.

The method of applying the test for amnesia which I use is as follows. Some object with which the patient is familiar is chosen: a convenient one being something from the infant's basket—a sponge, a comb—but any other, such as a key, or a penny, will do. The patient is gently roused, shown the object, and asked what it is. She will usually reply promptly, "A sponge." She is then allowed to fall asleep at once. About half an hour later she is again roused and asked, "What did I show you a little while ago?" If she promptly replies, "A sponge," she is not yet amnesic; if she appears to make an effort to remember and finally does so, she is on the verge of amnesia; but if fully amnesic she will say she does not know or will give some perfectly irrelevant reply, or perhaps do so by a counter-question. We have now attained the object in view, and as the testing proceeds during the progress of the labour a repetition of the scopolamine is needed if the patient appears to be on the verge of remembering the object shown, or if she does just recollect it, but not unless. These following doses will vary in amount as in the case of the second one.

During the progress of the labour it is most important to protect the patient from sensory impressions of all kinds, especially powerful stimuli such as loud noises, bright lights, etc. Unless

the patient happens to be near a noisy thoroughfare there is no need to use more than ordinary precautions to secure quietude. If there be any uncertainty on this point an oiled tampon of wool in each meatus will be enough. If the patient be suddenly roused from sleep or be allowed to recover her memory the incident and a few pains will probably be remembered. Gauss felicitously called this a memory island, and if a number of such occur the patient may reconstruct the whole of the labour from them and may aver she has never been asleep. Above all, nurses must be forbidden to help patients to bear down or handle them roughly. Patients will usually pass urine if told to do so, but if not they must be catheterized at suitable intervals.

Some obstetricians have expressed the opinion that they do not object to giving a patient one dose of scopolamine-morphine, but will not give a second even of scopolamine alone. This has nothing whatever in common with amnesic narcosis, is (to use a homely simile) neither fish, flesh, nor fowl, and will not be further discussed.

For a busy practitioner, however, who has not time to give the attention the above outline demands, there is a modified method, which, while not giving nearly the satisfactory results obtained by the above, may yet achieve about 60 per cent. of successes. The initial dose is given as before, and is followed by, say, 1/450 grain of scopolamine every hour. Not a few cases will recollect most, if not all, the labour, and occasionally one will even be overdosed, but on the whole a good deal of satisfaction can be got out of it.

Something must now be said about the more general effects on the patient, before dealing with those on the infant. The first is the onset of drowsiness, which often asserts itself quite early, usually well within an hour of the first injection. This merges insensibly into definite sleep and is accompanied by flushing—as a rule most marked on the face, but by no means always confined to it. By this time there is generally a pronounced slowing of the pulse, which invariably, provided the technique is correct, at least maintains its volume and character. This is due entirely to the shielding from shock and allaying the nervousness (that is, emotion) of the patient. It is my usual experience that a patient beginning labour with a pulse rate of 100 or over will finish the labour with it in the region of 70. At this time also the pupils are beginning to dilate and remain dilated to the end. This suggests a warning that we must be sure the patient really visualizes the object we show her when testing for amnesia. The uterine contractions continue, but as there is a diminishing demonstration on the part of the patient it has been assumed the contractions also diminish in intensity. I wish to say emphatically this is not so, as can be proved by abdominal palpation. In this connexion it may be added the labour is not prolonged. Those who assert the contrary do so either because they think theoretical considerations demand it or they have used a faulty technique. My experience, extending to over 700 cases, amply proves my contention. Nor is the expulsion of the placenta in any way interfered with, and certainly the incidence of post-partum haemorrhage is not increased. But as the patient usually sleeps from one to four hours after the labour she must be watched carefully, because if haemorrhage should occur she will not direct attention to the fact. The most striking after-effect on the mother is a remarkable well-being after the labour. Even the most contentious critic concedes this—indeed is compelled to do so.

It may be as well to say collectively that the main things to avoid are analgesia, restlessness, and a rapid pulse—a syndrome which is a certain indication of overdosing both patient and infant.

Should any operative interference, such as a forceps extraction, be necessary, it is better to give a little of some general anaesthetic, not because it is impossible to do this under omnipon-scopolamine alone, but because we obtain complete passivity of the patient—a very necessary consideration in any delicate manipulation. The quantity of a general anaesthetic needed to secure this end in most cases is surprisingly small.

After all, it is round the question of the interest of the infant that discussion has chiefly centred. Some observers have stated that the risk to the foetus is gravely increased, but as a rule alongside this statement there has been no exact description of the technique used. From what I have already said it may readily be inferred that the margin between amnesia and analgesia is very narrow, and with the least inattention or lack of skill it may easily be overstepped. This is only

another way of emphasizing the importance of the memory test. It has repeatedly been said that scopolamine-morphine causes asphyxia, and this with such an air of finality that one would almost conclude it is the only cause of asphyxia. Now the causes of asphyxia are very varied, and if scopolamine-morphine be used, to say that all the cases of asphyxia are due to the drugs is scarcely fair. This is not the place to analyse the figures given by Browne of Edinburgh in a very important and interesting investigation into the causes of death in 200 consecutive cases of stillbirth. The point of interest now is that in these 200 cases no cause of death could be found in two, and it was therefore attributed to scopolamine-morphine. In these two cases the mother had a second dose of morphine, a practice which is now discontinued in Edinburgh and a point on which I have already laid stress.

What occurs unequivocally in a number of cases is a condition of oligopnoea, a condition for which the opium derivative is at least largely responsible. As the operator improves in his judgement and is able to reduce the amount of morphine in suitable cases the incidence of oligopnoea diminishes. It is of course due to absorption of the drug through the placental circulation, and the condition is as follows: immediately on expulsion the infant utters a sharp cry and moves its limbs in the characteristic way, but these become abortive and the child lapses into sleep, the breathing at the same time becoming somewhat shallower and slower. It appears exactly as though the infant were tired, resented any interference, and wanted a little rest before taking on the serious responsibilities of life. If left to itself the child reverts to normal breathing within a short time, and, provided the condition is not accompanied by any cause of a definite asphyxia, no active interference is needed, nor, indeed, wise. So far from being harmful, I am convinced that oligopnoea does no more than shield the infant from the shock of a rough and prolonged passage through a non-resisting bony canal that is usually too small for it. We are apt to forget that an infant's voyage into life is often more stormy than is pleasant, and I am sure this treatment at least reduces the unpleasantness. Contrasted with a prolonged administration of a general anaesthetic the result must be considered at least favourable, for it is admitted the latter may distinctly jeopardize the infant.

In a short paper there are other interesting points which could not be introduced, but many of them have been discussed elsewhere, and I can only add in conclusion that those who have used scopolamine-morphine seriously—such as Buist, Sir Halliday Croom, Freeland and Solomons, Haultain and Swift, Hedley, Hendry, Webb-Johnson, Johnstone, and Nielholson—have a great measure of enthusiasm for it. They avoid any risks contingent upon overdosing by the adoption of a correct technique, and reap the advantages that are offered by no other anaesthetics or analgesics in labour.

II.—THE "STANDARDIZED-DOSAGE" METHOD OF USING SCOPOLAMINE-MORPHINE DURING LABOUR.

BY

N. HIRSCHMAN, M.D. Edin.

The following observations on 140 cases—63 primiparae and 77 multiparae—of morphine and scopolamine treatment were carried out in the Royal Maternity and Simpson Memorial Hospital, Edinburgh, in 1917. I have to thank my chief, Dr. J. W. Ballantyne, for kindly giving me the scope and allowing me to make use of the material in his term of office. I also have to thank him, as well as Dr. O. Nielholson, for their interest and encouragement while these observations were made.

I shall not dwell on the various criticisms offered against "twilight sleep" by the Berlin school, nor the various methods followed by other men. Most medical men are aware of the nature of this treatment in obstetrics. On the other hand, I know of doctors even now who have, whether in cases of primiparae or multiparae, given one injection of morphine and scopolamine "at any odd time during labour," say they have used "twilight sleep" in these cases, and, when unsuccessful or the babies badly oligopnoeic, become prejudiced and condemn the drug. It is a duty of every medical man practising midwifery to have a good idea of this treatment, if not actually to use it. If this drug is to be

used at all, however, a chance must be given to the busy practitioner who says "he has no time to waste over a confinement," and who, if he did, would only neglect the rest of his practice. The method adopted ought to be simple, and, if carried out by most of us, will have a beneficial effect on the falling birth rate. Just as we are beginning to realize that ante-natal treatment of pregnant women is important, so ought we to make more use of this drug, and by telling the woman who is to be confined that she will have "twilight sleep," thus, in many cases, ease her mind of a dread.

Premature delivery may even occur not only as the result of physical, but also of mental disturbance. The confinement under "twilight sleep," instead of becoming to the morbid woman a possible pathological condition, becomes really a physiological one in the true sense of the word.

In the method I have adopted—the "standardized dosage," as Dr. Greenwood calls it—I have tried to regulate the dosage so that it should dispense with the difficult "individualization" technique of Gauss, and allow a nurse of ordinary intelligence to carry out the doctor's instructions. Except in one case, where I had given a patient who had a very rigid os two doses of chloral—20 grains every twenty minutes—there was no necessity for the nurse to be actually alarmed and to call me.

Dosage.

During my observations I have used the following drugs and doses:

1. Multipara: Initial dose, 2/3 grain omnopon and 1/150 grain scopalamine, with an hourly injection of 1/450 grain scopalamine.
2. Primipara: Initial dose, 1/4 grain morphine and 1/150 grain scopalamine, with an hourly injection of 1/450 grain scopalamine.
3. Primipara: Initial dose, 2/3 grain omnopon and 1/150 grain scopalamine, with an hourly injection of 1/450 grain scopalamine.
4. Primipara: Initial dose, 2/3 grain omnopon and 1/150 grain scopalamine, with an hourly injection of 1/400 grain scopalamine.
5. Multipara: Initial dose, 2/3 grain omnopon and 1/150 grain scopalamine, with an hourly injection of 1/400 grain scopalamine.
6. Multipara: Initial dose, 1/12 grain heroin and 1/150 grain scopalamine, with an hourly injection of 1/450 grain scopalamine.
7. Primipara: Initial dose, 1/4 grain morphine and 1/100 grain scopalamine and 1/150 grain atropine, with an hourly injection of 1/400 grain scopalamine.

I have not repeated the initial injection except in one case where labour had stopped. In this paper I shall point out two main things—namely, that there is a definite "danger period," or "period of oligopnoea," approximately from two to three and a half hours after the initial injection of morphine, and that the combination of atropine, if it does not totally prevent this period, at any rate tends to give us fewer oligopnoeic babies.

Success depends upon the patient's lack of conception of pain after the confinement is over, with no unfavourable result to the child due to the administration of "twilight sleep."

It is advisable that I state here what I mean by the various terms "amnesia," etc., in order to show how I come by my results. After the effects of the drugs have disappeared the patient is questioned as to how much or what she remembers. One might say that this is simply an inversion of Gauss's "memory test" with certain limitations. I place my results in Class I, II, or III accordingly.

CLASS I: *Total Amnesia*.—The patient says she remembers nothing, and has consequently no conception of having had pain during labour.

CLASS II: *Partial Amnesia*.—The patient has perception of pain or recollection of pain during the labour.

CLASS III: *No Amnesia*.—The patient recalls all events in full detail and recollects having had—

(a) No pain—complete analgesia or hypalgesia, as Greenwood calls it.

(b) Mitigated pain—partial analgesia.

(c) Usual pain—no analgesia.

Of course a primipara could not very well refer to pain as "usual." She is therefore asked whether the pain was unbearable or not.

One cannot always tell the ultimate result from the notice the patient takes of the prick of the needle or from her behaviour. There might have been or there may be an "islet of memory" formed. I have seen patients speak and act quite rationally while under the drug and yet remember nothing when questioned after the labour. On the other

hand, I have seen cases where apparently no "islets of memory" were caused, and where the patient was drowsy, talking nonsense very often, resulting, if not in a failure, at any rate not in a complete success. Of course, a patient might even tell a deliberate lie. I mention this because I had one case—a primipara—in private practice to whom I had given seven injections. This might, on the other hand, be due to the fact that the patient was never really under the influence of the morphine and that numerous "islets of memory" were formed.

RESULTS.

First Series (Multiparae, 11 Cases).

The cases in this series had an initial dose of 2/3 grain omnopon and 1/150 grain scopalamine, with an hourly injection of 1/150 grain scopalamine. Average number of injections 4.18. Three of the cases were in Class I, 5 in Class II, and 3 in Class III. Five cases had no pain, and the pain was mitigated in 6. Three of the cases had no chloroform at the end of the second stage; 2 cases had only one injection. Both these facts tend to make the percentage too low. There were no restless patients. Four babies were oligopnoeic, but recovered. The first was born spontaneously 2 hours 40 minutes, the second 2 hours 5 minutes, and the third 3 hours 55 minutes after the initial injection; the fourth was a "forceps case" for contracted pelvis. Subtracting this last, the oligopnoeic babies = 27.2 per cent. All the babies were born alive.

Second Series (Primiparae, 13 Cases).

These cases were treated initially with 1/4 grain morphine and 1/150 grain scopalamine, followed by an hourly injection of 1/450 grain scopalamine. Average number of injections 6.5. Eight of the cases were in Class I and 5 in Class II. There was no pain in 9 of the cases, and in the 4 remaining cases it was mitigated. Two cases had no chloroform. One patient was very restless. Five babies were oligopnoeic, but recovered. One was born spontaneously 22 hours after the initial dose, and took 15 minutes to cry. Of the four remaining, three were stiff "forceps cases" and the other was a dry labour. There were six "forceps cases." All the babies were born alive. In this series three babies, besides the one mentioned above, were born in the "danger period"; all were lively. I shall refer to this later. One patient had twenty-six hourly injections; she delivered herself spontaneously, the baby being quite lively.

Third Series (Primiparae, 6 Cases).

These patients received an initial dose of 2/3 grain omnopon and 1/150 grain scopalamine, followed by an hourly injection of 1/450 grain scopalamine. Average number of injections 6.8. Five of the cases were in Class I and the other in Class II. In five of the cases there was no pain, and pain was mitigated in the other. One patient had only one injection. There were no restless patients, and none of the babies were oligopnoeic. Of six babies, five were alive and one was a craniotomy. There were three "forceps cases," one for contracted pelvis.

Fourth Series (Primiparae, 30 Cases).

The patients in this series were treated initially with 2/3 grain omnopon and 1/150 grain scopalamine, followed by 1/400 grain scopalamine every hour. Average number of injections 7.2. Twenty-five of the cases were in Class I, 3 in Class II, and 2 in Class III. No pain was experienced in 26 cases, mitigated pain in 2 cases, and "usual pain" in 2 cases. Six cases had no chloroform; 3 cases had only one injection. These facts lower my percentage of successes. Two patients were very restless. Four cases had chloral for rigid os, one having three successive doses, each 20 grains, every twenty minutes. One case had a total of 36 injections, but the treatment was discontinued twice in three days on account of labour stopping on each occasion. There were eleven oligopnoeic babies: one baby was born spontaneously 1 hour 35 minutes after the initial injection and was very oligopnoeic; a second was born spontaneously 3 hours 20 minutes after the initial injection, also oligopnoeic, as well as another 4 hours after. Of the remaining eight, there were six "forceps cases"—three stiff ones—and two breeches. Excluding the three stiff "forceps cases" and the two breeches, in which there was delay in the for large babies, we get five oligopnoeic babies. As soon as no chloroform is given or injections are begun late we get a smaller percentage of successes and a higher percentage of oligopnoeic babies. Of thirty babies, twenty-eight were born alive, the other two being unavoidable craniotomies. There were eight "forceps cases," of which two were for large babies—one an impacted shoulder.

Fifth Series (Multiparae, 62 Cases).

These patients were given an initial dose of 2/3 grain omnopon and 1/150 grain scopalamine, with an hourly injection of 1/450 grain scopalamine. Average number of injections 6.5. Five cases were in Class I, 5 in Class II, and 52 in Class III. Pain was experienced in 10 cases, and "usual pain" in 5 cases. Five cases had no chloroform, 15 cases had only one injection; 2 cases were very restless; 4 cases had chloral. Seven babies were born in the "danger period"—2 to 3 hours after the first injection; all of these were born spontaneously; all were badly oligopnoeic, but recovered. There were eleven other babies oligopnoeic. Of these, seven were "forceps cases" for contractions or large babies, and one a difficult breech. Excluding those, we get ten oligopnoeic babies. In 62 cases there were 63 babies (one case of twins). One, an anaemic patient, died in twenty minutes. There were three dead babies, of which one was macerated, the second was due to a severe accidental haemorrhage

from a fall, and in the last the mother, after a fall, had not felt life for three days before admission; this was a "forceps case." There were altogether thirteen "forceps cases," of which seven are mentioned above, two prolapsed cords requiring interference, and also in the case of the large child which was dead-born. Thus we get three "forceps cases" apparently due to scopolamine-morphine. (The small hospital percentage here was no doubt due to the fact that I was administering pituitrin in a bigger percentage of cases.)

Sixth Series (Multiparae, 4 Cases).

These four patients received an initial dose of 1/12 grain heroin and 1/150 grain scopolamine, followed by an hourly injection of 1/450 grain scopolamine. Average number of injections 5.2. Three of the cases were in Class II and the other in Class III. In one case there was no pain felt, and in the other three the pain was mitigated. All the patients had chloroform. There were no restless patients. One baby was born 2 hours 25 minutes after the initial injection, but was quite lively. This, in my opinion, shows that the morphine in the initial dose was too small to cause any oligopnoea in spite of the baby being born in the "danger period." For the same reason the total successes are small. There were no dead babies and no "forceps cases."

Seventh Series (Primiparae, 14 Cases).

The patients in this series were treated initially with 1/4 grain morphine, 1/100 grain scopolamine, and 1/150 grain atropine, followed by an hourly injection of 1/400 grain scopolamine. Average number of injections 6.4. Thirteen of the cases were in Class I, the remaining case being in Class II. No pain was felt by thirteen of the patients, and only mitigated pain by the fourteenth. One patient had no chloroform; one was very restless. Four babies were born in the "danger period," but all were lively; this, I am sure, was due to the fact that 1/150 grain atropine was added to the initial dose. (A larger dose of scopolamine was used.) The other cases had only 1/150 grain scopolamine. Thirteen babies were born alive and one dead, the latter being born spontaneously; it had blood in its mouth and nose, was very badly nourished, and the coils of the cord were thin and few. There were two "forceps cases."

Apart from the different doses used, if we take "twilight sleep" as having been used in 140 cases of multiparae and primiparae we find that there were 141 babies born, of which 7 were dead—3 unavoidable craniotomies, 1 macerated foetus, 1 due to severe accidental haemorrhage (Series V), 1 in which the mother felt no life for three days (Series V), and 1 where the baby was badly nourished (Series VII). This gives us 134 live babies, of which one, an anencephalic, died after twenty minutes. If the last three are considered as being due to the treatment, we get 2.1 per cent. of dead babies. If the last one only is considered, then we get 0.74 per cent. dead babies. The high percentage of "forceps cases" is unavoidable where the institution is one for teaching purposes. Besides that, when the second stage has lasted about two to three and a half hours the patient is as a rule delivered with forceps. Another point to be considered is that when the patient is admitted to a public hospital and is in labour, she is given a bath first before being brought to the labour ward. Injections are therefore given very late, the pains being usually severe.

Results Compared in Different Series.

In comparing the results in the different series, I to VII, it is easily seen that a higher percentage of successes is found in the cases of primiparae. It is certainly due to the fact that labour is more prolonged, thus necessitating a larger number of injections and so conducing to a better amnesic and analgesic effect. For the same reason we find that, in a percentage of multiparae, only one or two injections are given with not such a good effect apart from any idiosyncrasy to the drug. As regards the primiparae, the percentage of successes is raised and that of failures lessened. Those primiparae treated with 2/3 grain omopon and 1/150 grain scopolamine show a much better result than those treated with morphine and scopolamine. The omopon also seems to have a less toxic effect, not only on the patient but also on the foetus. The scopolamine has a quicker effect, and when the babies are born, they are a good deal less blue. Heroin 1/12 grain is certainly too small a dose for an initial injection. Although the percentage of complete successes is small, the partial successes are fairly good. In Series VII, the addition of atropine 1/150 grain has had a remarkable effect. The result here contradicts Dr. Innes and others, who used atropine in their cases. Any toxic action the morphine has in the mother or child seems to be counteracted by this drug. The fact that the babies born in the "danger period" were not oligopnoeic is not, in my opinion, due to mere coincidence. The forceps cases were also less (compare, for example, with Series II); the restless patients gave as little trouble as the others, if not less than usual. There were no absolute failures.

Complications.

Restlessness may occur not only after giving two or three injections of scopolamine but also after twenty, thirty, or more. It is not always due to an idiosyncrasy of the patient to the drug, but very often to faulty technique or carelessness on the part of the attendant in ministering to the patient's needs. In every case I have found that there is thirst to a greater or less degree. Even when the patient does not ask for a drink, small sips of water or milk, especially if she is restless, ought to be given. Apart from actually giving fluid, the face, lips, and gums of the patient should be constantly moistened by the attendant. Especially when the head is on the perineum, the patient is very apt to put her hands down to the vulva during a pain. If sepsis is to be avoided, this particularly should be prevented. The nurse should be very careful not to allow the bladder to become distended, for obvious reasons, and should persuade and encourage the patient to pass water at regular intervals, depending on the quantity of fluid taken and the length of the labour. If necessary a catheter should be passed. The patient will not always ask for what she wants.

Effects on the Mother.

The nurse ought not to hold a conversation with the patient in any way except in so far as is essential. Some patients talk quite rationally, are not much flushed, the Babinski sign and pupil reflexes may be absent, muscular co-ordination may be good, and yet they may turn out to be very good cases of "twilight sleep," and vice versa. The value of suggestion on restless patients is very notable. I have seen very restless cases, where I have suggested that "they are tired and want to sleep," become absolutely calm. I have never had occasion to discontinue treatment in these cases, nor have I observed any active or muttering delirium. It is probably faulty technique. In a few cases, as mentioned previously, where the os has been very rigid, I have given chloral in 20-grain doses every twenty minutes up to three doses if necessary, before starting on the morphine-scopolamine. The dose is certainly heroic, but the doctor ought not to leave the case during the time. It has one advantage—namely, that the patient does not realize when she is getting the initial dose of morphine-scopolamine, this fact tending later to make the case more successful. The patient ought in all cases to have chloroform at the end of the second stage, in order that she should not retain any idea of the labour from an "islet of memory" being formed, due to the more intense pain.

A remarkable after-effect on the mother is the absence of shock and exhaustion, either subjectively or objectively, occurring not only in short labours but also in lengthy complicated ones. This necessarily tends to make the convalescence quicker and more pleasant, inasmuch as nervous energy is conserved. In most cases of multiparae, if morphine 1/4 grain or omopon 2/3 grain is to be given it should, even at the risk of labour stopping again, be administered at the very beginning, judging only from the state of the os, and not from the actual severity of the pain. It is well known that some multiparae will often not have acute pain until the os is fully dilated or even the head on the perineum. If there is any reason to anticipate a fairly rapid course of labour, and a risk of the child being born in the "danger period," a smaller dose of morphine or omopon than usual should be given, with more frequent injections of scopolamine or a larger initial dose of scopolamine. The dose of morphine is the governing factor, and unless this be given before the pains become acute no complete success need as a rule be expected.

One great disadvantage I must mention, apart from any method adopted. With the average general practitioner who treats patients with "twilight sleep," and who has not had a very great experience of this drug, vaginal examinations, particularly in multiparae, are necessarily increased. This is a fact even with his more experienced colleagues. If puerperal infection, caused as a rule by sepsis from without inwards, is to be avoided, and the percentage of deaths lessened, then it is the duty of everyone using this treatment to be particularly careful, and not give occasion for further criticism on the part of those who already condemn the drug.

Effects on the Child.

I do not think it is necessary to listen to the foetal heart any more than in cases not treated by morphine-scopolamine. Any cause for anxiety that there is—apart from the child being born in the "danger period" (this not being a real

(danger)—depends on other complications. The baby, no matter what success or failure the case has been, is always more or less blue. There is never really that pink colour seen. Scopolamine babies invariably seem to have more viscid mucus in their throats than those born otherwise. I make it a rule in every case where the child is not lively to ligate the cord immediately and use a mucus extractor. Of twenty-three babies born spontaneously up to two hours after the initial injection only two were oligopnoeic. Judging by what the nursing staff told me in the hospital, the scopolamine babies seem more quiet and contented than any others. Whether this is merely the imagination of enthusiasm or not I am not prepared to say. It is, at any rate, a known fact that the drugs are excreted by the child in a few hours, so one cannot say that the babies are still stupid from the effects of the drug.

Conclusions.

On looking through my results of morphine-scopolamine treatment on 140 cases carried out in the Royal Maternity and Simpson Memorial Hospital, I have come to the following conclusions: It is the morphine which causes the analgesic effect in the mother primarily, and allows the scopolamine to take effect. A second dose of morphine is not necessary, but where for any particular reason the doctor thinks it is required he should make quite certain, first of all, that the child is not likely to be born in the "danger period"—namely, from two to three and a half hours after the last injection of morphine. If it is born in that interval it will be very oligopnoeic. A smaller dose of morphine—for example, heroin $1/12$ grain—although likely to cause little anaesthesia or analgesic effect in the mother, will not cause this oligopnoea. The reason I use the word "danger" is in order to keep the doctor on the *qui vive* and make him realize this period before commencing treatment. The baby born in this period may not be in any apparent danger, but will likely cause some anxiety before it breathes properly and cries.

The "danger period" can be avoided by combining a dose of atropine—for example, $1/150$ grain—with the initial injection of morphine-scopolamine. From the similarity of its action to scopolamine and its effect on the brain, I think the amnesia becomes more pronounced, at the same time preventing the toxic action of the morphine. If, knowing that the atropine is an antidote to morphine, we allow the latter to act first for half an hour and then inject the atropine, we might get a still better result. Although I have used different doses—"standardized dosage" method—in treating the primiparae and multiparae in the 140 cases, I have seen that the initial dose of morphine $1/4$ grain, scopolamine $1/100$ grain, and atropine $1/150$ grain, followed by scopolamine $1/400$ grain hourly (mentioned in Series VII), is the best from every point of view. The babies in a set of 14 primiparae were all lively; the "forceps cases," apparently due to the treatment, in comparison with those known to be from a definite cause like contracted pelvis, were less so. (Instead of morphine $1/4$ grain, I think $1/2$ or $2/3$ grain omopon would be better.)

The initial dose of scopolamine ought always to be $1/100$ grain, apart from any idiosyncrasy of the patient to the drug, although, as I said before, the initial dose of morphine is the governing factor in multiparae. The initial dose of morphine should be from heroin $1/12$ grain to omopon $2/3$ grain, depending on how long labour is expected to last. It is certainly advisable, although not essential, to have a nurse in attendance who has seen the effects and nursed cases of "twilight sleep." She must be in constant attendance upon the patient, not leaving her alone for a moment.

The morphine-scopolamine treatment is particularly indicated in primiparae and in cases where a lengthy, severe labour might be expected. If puerperia is to be given at all during the labour, it is certainly less torture to the patient to be under morphine-scopolamine narcosis or semi-narcosis than otherwise. A little chloroform before giving the first injection certainly helps to make the patient drowsy, but this is inadvisable, as many people, particularly primiparae, cannot bear the smell of this drug. The "standardized dosage" method is to save the doctor trouble and allow him to go about his other duties. For the same reason whiffs of chloroform for restlessness are out of the question. Chloroform should, however, be administered at the very end of the second stage, not only for obstetrical reasons, but also because it prevents "islets of memory," or impressions, on the brain.

I am sure, no matter which method is followed, that in most cases of "twilight sleep" there is not that complete alertness

and desperation present when the patient has to bear down. This would no doubt tend to make "forceps cases" more frequent. Puerperia, however, overcomes this disadvantage as a rule. The advantages in using the treatment outweigh the disadvantages by far. With ordinary reasonable care there certainly need not be any untoward effects on the mother, and very little, if any, on the child.

Post-partum haemorrhage and manual extraction of the placenta do not occur more frequently than usual. There are some who say that this treatment is liable to cause some defect or ill effect later in the child. I can only say that I have had an opportunity in private practice of observing the babies born under the treatment, and they were all apparently healthy and bright. Looking at morphine-scopolamine treatment from an ante-natal point of view, I think it is an unquestionable fact that the thought of having this treatment is bound to react favourably on the mental and physical condition of the mother, and therefore on the child. If we have to consider the ante-natal care of a pregnant woman, we must try and ease not only her physical symptoms, but also, in those who dread and fear the impending labour, as mentioned previously, their mental symptoms as well.

III.—ON THE MAINTENANCE OF "OBSTETRIC ANAESTHESIA" BY MEANS OF INFUNDIBULIN AND CHLOROFORM.

BY

A. F. MARTIN, M.D., Ch.B.Vict.,
Bradford.

It is not now too much to say that sufficient anaesthesia to dull the pains of labour to the point of complete amnesia can be maintained without the use of morphine or hyoscine or other alkaloid, and without their attendant tedious pretraction of labour. After considerable experience I may say that to the busy general practitioner the disadvantages of the alkaloid method are: (1) that it undoubtedly does lengthen labour by making the pains less frequent and weaker, and by making the patient so drowsy that she cannot help herself by her own efforts of expulsion, thus rendering forceps operations more frequent; (2) that unless the first dose is given at the right time the uterine reflex will not be denied, and it is often impossible to obtain an amnesia.

The method to be described makes labour pains stronger and more frequent, does not deprive the woman of her expulsive powers, and can be begun at any time during the course of labour.

It is universally admitted that chloroform, unaided, defeats its own ends in midwifery by sacrificing the efficiency of the pains. But if the uterine reflex is kept active by repeated small doses of infundibulin, while a light chloroform anaesthesia is maintained, our aim of a virtually painless unimpeded childbirth is realized.

The peculiarly favourable behaviour of the parturient woman to chloroform has never been satisfactorily accounted for. If a Junker inhaler be used a fineness in regulating the degree of anaesthesia can be obtained which is not possible by the open method—namely, a state in which the corneal reflex is not abolished but dulled, where the woman still "bears down" to her pains and yet remembers very little of them, in spite of their accentuated and augmented recurrence. But I had never succeeded in maintaining this condition until about three years ago, when I began to realize that the pituitarized uterus could maintain itself against the numbing effect of chloroform.

The technique I have used is as follows:

Having diagnosed an anterior presentation and ascertained that dilatation is fairly full, and that there is no undue disproportion between the child's head and the maternal parts, $1\frac{1}{2}$ c cm. of infundibulin is injected intramuscularly, and, when the augmentation of the pains is seen to begin, chloroform is given through a Junker inhaler attached to a mask, which was secured earlier to the woman's face, she lying in the usual position on her side, the pulling on a strap. The chloroform is continued as long as the pain lasts, and then stopped, and given again at the onset of the next pain.

The infundibulin stimulates the activity of the uterus so markedly that this amounts very soon to maintaining the light anaesthesia described above. As the effect of the infundibulin wears off the chloroform begins to be the predominant factor, and the vigour of the pains abates. This usually happens by the end of half an hour or so. Now one renews the infundibulin, and continues as much chloroform as is

thought necessary. A little practice will soon enable one to judge of the depth of anaesthesia needed to produce amnesia. This *modus operandi* can be kept up indefinitely, the effect of the pains being watched, while the accoucheur sits at the foot of the patient, pumping his chloroform through a long tube to the facepiece at the patient's head. Single-handed chloroform by the open method can easily become a haphazard procedure.

I have often given 2 c.cm. of infundibulin in two hours, and several times 3 c.cm. in three hours, but have never exceeded this dose, and only once given more than 0.5 c.cm. in a dose, which Dr. Blair Bell, in a very kind letter to me, agrees is non-toxic. His opinion is, however, that a dose of 3 c.cm. should not be exceeded until after twelve hours have elapsed. My impression is that an unusual increase in the pulse rate is observed in a few cases towards the end and after labour, but there are no definite toxic effects of multiple dosage up to the above limit to either mother or child, if ordinary care is used.

Another question arises as to whether, infrequently, infundibulin is a factor in the causation of post-partum haemorrhage. I can imagine that when the infundibulin is unduly active, and placental separation is violent and rapid, more venous sinuses would be open at one time, and the clotting of the blood less complete than when separation is more deliberate, and thus haemorrhage be more abundant.

And again, does prolonged chloroform anaesthesia interfere with the clotting power of the blood? Undoubtedly it does, but it must be remembered that, in this procedure, the chloroform anaesthesia is only very light, and the amount used insignificant—never more than 1½ to 2 oz. in two or three hours, and since I have used a Junker inhaler, as suggested to me by my friend Dr. Carroll, I have found the amount used has been much less. In any case an injection of haemoplastin early in what promises to be a prolonged case should ensure safety. In only one instance have I had some post-partum haemorrhage in thirty-three labours conducted in this way, and this was in spite of the uterus being firmly contracted, and in spite of the absence of laceration from overaction, as ascertained subsequently. The indications for forceps remain as in unaided cases, but the incidence of forceps operations has steadily decreased since I have adopted this practice. I have only had to use forceps twice, both for primiparae—once in 1920 and once in 1921—both for delay of the head for over half an hour, in spite of regularly recurring pains. It has seemed to me that the chloroform helps to undo the spasmodic involuntary tightening of the maternal parts which occurs in nervous women during severe pains. This and the increased uterine action account for the rarity of forceps operations.

In occipito-posterior presentations delivery is obtained without the aid of forceps by rotating the head and, at the same time, turning the body by the shoulder into the anterior position under full chloroform. The head is held by the hand that has turned it until the pains, abolished by the chloroform, have been re-established. This is attained in a few minutes by the nurse giving a previously prepared dose of 1 c.cm. The effects of the chloroform will prevent any uterine overaction, and the brisk uterine contraction will fix the foetus in the anterior position. I have notes of four such cases, and these are the only occasions on which one has given a full cubic centimetre. All four have been delivered without forceps.

When the head is stretching the perineum and not receding, the force of the pains can be checked by increasing the amount of chloroform used, and extensive rupture often avoided. Lind Smith¹ agrees that chloroform modifies the effect of infundibulin, and recommends repetition of the dose. I have notes of 32 cases, taken over three years for my own guidance, long before I thought of publication. Most have had three 1½ c.cm. injections, some two, and one only one. Others, where I was earlier on the scene, or where longer labour has ensued, have had five or six injections, and labour has lasted three hours. One of my patients, an intelligent woman, who has had three scopolamine-morphine labours, said she much preferred the infundibulin-chloroform method. She had three injections, labour lasted one and a half hours, and she voluntarily told me that loss of memory had been more quickly obtained and was more complete with the latter. The only danger lies in overdosage of chloroform; this is minimized by using the Junker inhaler. I make it a rule always to avoid heavy stertorous breathing.

I can confidently recommend this procedure as being superior to the alkaloid method in general practice. I have seen no bad results to either mother or child.

A few illustrative cases may be acceptable.

CASE I.

Mrs. S., aged 35; 2-para. Infundibulin 2.5 c.cm. injected in one and three-quarter hours; 1 oz. of chloroform used through a Junker inhaler. The amount used here was rather large, but one knew the uterine pains were poor and infrequent during a very tedious day eight years ago at the first labour, which ended with a hard "it the infundibulin was repeated when the mother more freely than is usually necessary. no remembrance of the second injection or afterwards.

CASE II.

Mrs. F., aged 28; primipara. The first injection was given when the os was the size of a crown piece, very soft, and distending well with a good bag of membranes. The membranes did not rupture until after the third injection; 3 c.cm. of infundibulin were used in three hours. Complete amnesia was obtained, although for two hours the patient pulled on the strap and bore down to her pains. Two ounces of chloroform—open method—were used.

CASE III.

Mrs. H., aged 39; 2-para. First dose just before the cervix was fully dilated; repeated at half-hourly intervals; 1½ oz. of chloroform used in two hours—open method. No remembrance after second injection. No bleeding. Pulse quick after labour, but settled down after the one necessary perineal suture had been put in. This patient was sent home from India with amoebic dysentery, and was a wreck at seven months, but her general condition was quite good at the time of labour; a quick pulse after a two hours' labour and some undue pallor is explained apart from the anaesthesia. Scopolamine-morphine was absolutely without effect when used for her first baby five years before.

CASE IV.

Mrs. E., 2-para. Delivered in two hours; 6 drachms of chloroform by Junker inhaler; 2 c.cm. infundibulin. The pulse was always too quick—about 100 very early in labour between the pains, and later 108. She had had twenty-four hours of ineffective pains before dilatation was on the way, was anaemic and not in good condition. The mother told me afterwards she had not been well throughout the pregnancy. I should not have begun the treatment without weighing up the probabilities. She can remember three injections and some of the pains. This was the same with scopolamine-morphine, which had to be abandoned at the first confinement owing to uterine inertia and quick pulse, and completed with infundibulin and chloroform. She vomited all night after confinement, kept a small pulse, and had much after-pain. Although the uterus contracted firmly post-partum haemorrhage was too excessive, but the placenta seemed huge. It weighed after draining the blood from it 1 lb. 10 oz., and measured 9 inches by 8 inches. It can be argued that this post-partum haemorrhage would have occurred in any case, and was due to large placenta and poor general condition.

This is the only set-back I have had, and made me vow never to give this anaesthesia in labour without carefully considering the case before beginning, and never to promise uncreservedly to use it beforehand. She had a slow pulse two days after, and never looked back. Examination at the end of a month showed a perfectly regularly closed os, and no other abnormality. She was a case, where the stage of light anaesthesia is the memory of the pains. Her satisfaction—deeper anaesthesia.

CASE V.

Mrs. H., 2-para. Infundibulin 2 c.cm. used in two hours, and only 3 drachms of chloroform, with Junker inhaler. Patient says she can remember some of the pains. Too little chloroform was used here.

CASE VI.

Mrs. S., 2-para (midwife's case). Three hours' delay in pelvis. Occipito-posterior presentation diagnosed; head rotated and held; 1 c.cm. of infundibulin used. Firm uterine action five minutes later. Spontaneous delivery.

I have noticed several times, where the uterus has contracted very violently, the tail of the membranes is held, being caught in the enfolded uterus. The tail, stretching with the weight of the still attached placenta, eventually may break, and quite a large piece of membrane can be left behind it, after the placenta is delivered, any tension on the membranes is allowed when they are felt to be held. The safe thing to do is to secure the tense cord of membranes with a Spencer Wells forceps, cut the placenta and distal main part of the membranes away, so avoiding tension, and allow the tag to come away when the uterine contraction slackens.

Conclusions.

1. The woman in labour, being peculiarly amenable to the action of chloroform, can be rendered amnesic by maintaining a light partial anaesthesia, which is harmless to mother and child, if the uterus be kept active by means of repeated small doses of infundibulin.
2. Usually 0.5 c.cm. of infundibulin, every half-hour or so, is enough, the chloroform being administered with the onset of and during the pains.

3. A Junker inhaler is a valuable help in avoiding the use of too much chloroform and regulating the dose. The amount used will vary, 3 drachms in the hour being the least with which I have obtained a satisfactory amnesia.

REFERENCE.

DISCUSSION.

The PRESIDENT said that personally he fully admitted that all the results claimed could be substantiated, but he thought that the matter was essentially one for discussion by general practitioners; it might even in time become a subject for consideration by midwives, though he certainly would not advocate that at present. Still, considering the many commitments of a man in busy practice, might not the carrying out of the treatment often be left to the nurse?

Dr. LAPHORN SMITH had observed that in one town the most successful practitioner was one who gave his confinement cases morphine. He thought the suffering in the early stages of labour was generally due to fear. He advocated sodium bromide and opium particularly for primiparae when the pains commenced in the middle of the night. Another excellent prescription was acetanilide in 5-grain doses, given in a cup of hot coffee for three doses at least. He had tried the scopolamine-morphine method but had given it up, owing to a great increase in the number of cases causing anxiety after its use. He suggested the substitution of can-de-Cologno for the alcohol in the ordinary A.C.E. mixture; it made a very pleasant anaesthetic. For the past thirty years in every case to which he had been called in time he had administered an anaesthetic. He entered a protest against the use of the term "twilight sleep," as it had become commercialized.

Dr. CHALMERS thought that Dr. Martin did not bring his forces into play until the period of greatest anxiety was passed. He was in favour of omuopon and scopolamine, but agreed that if morphine were given within six hours of the birth of the child trouble with the child might be anticipated.

Dr. RUSSELL ANDREWS gave a warning about pituitary extract. He said that standardization of this preparation was at present in a state of utter chaos: strengths varied to an enormous degree. If the weakest brand was called 1, then the strongest had been found to be 80, yet the dosage was given as the same in both preparations.

Dr. RUXTON spoke as a general practitioner and a physician to a lying-in hospital. He had found very little demand for scopolamine-morphine treatment even among the highly educated. His view was that in private practice the complete scopolamine-morphine technique was not practicable. Those who asked for it should go into an establishment where the whole thing was thoroughly understood. He advocated the old-fashioned treatment—an injection of morphine in slow cases was the best. He was convinced that the great principle "wait and see" was indicated in all cases. He asked for guidance whether it was safe to use scopolamine-morphine in diabetic patients.

Dr. BLAIR, speaking as a general practitioner of thirty years' standing, said that he had had 120 cases of "twilight sleep." He had now abandoned it, as he had found that it was impossible to carry out the method properly in a scattered area. His practice lay in an area of 300 square miles. In addition, there were, he thought, certain dangers in the practice; for instance, he had had two cases of very bad puerperal mania. He had now gone back to the old treatment—a dose of opium if seen in the early stages, to be repeated if necessary. He had abandoned "twilight sleep" as there were no advantages in employing it. He had had a great deal of trouble with his babies, and he could see no compensations in the use of this method by busy general practitioners.

Dr. LAMOND LACKIE said that he had used morphine-scopolamine narcosis in hundreds of cases, and he was a strong believer in the treatment. Dr. Ruxton had said that the great thing in obstetrics was to "wait and see." With that Dr. Lackie entirely agreed, and the greatest advantage of "twilight sleep" was that it allowed one to wait and give nature a chance with the minimum of suffering to the patient. His record showed that in 50 per cent. of cases the treatment was an unqualified success, in 30 per cent. it was only partial success, and in 20 per cent. it was a failure. There

were never any ill effects to the mother. Occasionally one met with a case in which almost a maniacal condition was produced, but this was temporary and passed off with the cessation of the treatment. The effect on the baby was, no doubt, sometimes disturbing and even alarming, but there were only two cases in the records of the Royal Maternity Hospital, in which the death of the infant was attributed by Dr. Browne, the pathologist, to morphine-scopolamine narcosis. The effect on the doctor was that it often gave him a good night's rest when otherwise he would have been in constant attendance upon the patient. A good nurse was easily trained to carry out the treatment and to give the injections intelligently.

Dr. PRELL said that it was not his successful cases that made a doctor's reputation, but the way he could cover up his failures. He pleaded for a higher degree of co-operation between the doctors and the midwives. He thought that many doctors might be deterred from testing the omuopon-scopolamine method as the other doctors in his district would not try it.

Dr. MILLER said that he had no experience of the "twilight sleep" method. In the Highlands they practised other forms of treatment during labour, with the result that nature was mostly trusted to, and nature was highly successful.

Dr. THOMAS absolutely agreed with the previous speaker. He asked, if there were such a thing as natural labour, why was there all this talk about interference?

Mr. HENDRY described how the term "twilight sleep" came to be adopted by the public press. Referring to dosage, he quoted Gauss as saying that if he were shown the standard woman he would say what the standard dose should be. Individuals differed markedly. He did not think that the best results could be obtained by giving table doses; doses must be varied to suit each individual. In regard to mania, some 4 to 10 per cent. of his cases had shown varying degrees of restlessness, but he thought that with careful dosage this could be avoided. The effects on the child were probably produced by some derivative of morphine. Frequently the child was born in a state of apnoea, but in his experience they always came round without the need for any active interference.

Dr. EDEN said that he had listened with the greatest delight to the remarks contributed by the general practitioners. They were packed with common sense, whereas often the remarks of the specialists were not. They could not all expect to obtain the splendid results of Dr. Greenwood. He did not think that Dr. Martin's method came into conflict with the scopolamine-morphine method; rather it was a method for shortening the second stage, and he questioned the wisdom of doing this. He could not say that he was greatly in favour of "twilight sleep." Special hospital "stunts" could not be applied in general practice.

Dr. GREENWOOD, in reply, said that he would not trust any nurse to carry out the treatment. The doctor should visit the patient at least once an hour. The bad results all came from pushing the drugs beyond their obstetric dosage. Analgesia was not required, only amnesia. He could not emphasize too strongly that they must carefully watch each patient. He thought it was the duty of the profession to shield the patient in labour by every means possible. Pain, fear, shock, exhaustion must be diminished as much as possible. Labour should be tackled in the same spirit as the surgeon tackled his difficulties. It was not a question of supply and demand by the patient. He had no experience of giving scopolamine-morphine in diabetes, but on theoretical grounds there was no contraindication, and he would not hesitate to employ it if a case presented itself. As regards extreme restlessness and mania these cases were certainly a sign of faulty technique. Restlessness, analgesia, rapid pulse were danger signals. He thought the giving of opium was a distinct menace to the child, and in many cases of eclampsia the child died from the effects of the morphine and not the toxæmia. He could not agree that "twilight sleep" prolonged labour—if it did, it was a sign that the technique was at fault. His experience was that in many cases labour was actually shortened, as the patient would permit the full contraction of her voluntary muscles, and thus assist the involuntary muscles to expel the child.

THE TREATMENT OF ECLAMPSIA.

BY

THOMAS WATTS EDEN, M.D., F.R.C.P.

Obstetric Physician, Charing Cross Hospital.

ECLAMPSIA has long been recognized as one of the most formidable of the risks of child-bearing. It is, however, of comparatively rare occurrence. Its frequency in hospital practice is about 1 in 125 labours, but this figure is, of course, higher than its average frequency, because a great proportion of the cases which occur are sent into hospital. The reports of the Registrars-General for Great Britain and Ireland for the ten years 1911-20 show that the average number of deaths per annum returned for puerperal convulsions was 630, the annual total varying from 733 to 551. From statistics which will be presently quoted it may be taken that the average mortality of the disease in Great Britain and Ireland is 22.5 per cent. Accordingly, the total number of cases occurring annually is about 2,800. Of this number something like 1 in every 4 or 5 dies. About 70 per cent. of eclampsia patients are primigravidae, and it follows that this disease takes toll in this country of the lives of about 450 young mothers bearing their first child every year. No better reason for discussing the treatment of this disease at this meeting could be advanced than is supplied by these figures.

A brief retrospect of the methods of treatment which have been in vogue at different times, will perhaps be useful, in order to explain to some extent the confusion which still exists. Previous to the discovery of albumin in the urine in eclampsia in 1843, the credit of which is due to a London obstetrician named Lever, the treatment was solely empirical. The detection of albumin in the urine appeared to the men of that time to stamp the condition as primarily a disease of the kidneys. This view was held, in one form or another, until the toxicæmic theory arose, by which the renal lesions were relegated to a secondary place, although their clinical importance was not thereby much diminished.

From 1843 up to 1870 treatment, generally speaking, consisted in: (a) venesection, repeatedly in some cases, unless contraindicated by marked anaemia; (b) morphine or opium in cases where venesection was contraindicated; (c) ice-cap, cold packs, or cold baths, wet cupping the loins, etc.; (d) no obstetric interference. There are no statistical results from this period.

From 1870 to 1890 treatment was still entirely expectant, narcosis and diaphoresis being mostly relied upon. Pilocarpine played a large part, and venesection was largely abandoned, as Schröder pointed out that the blood pressure rose again very rapidly afterwards, and the only lasting effect was to deprive the patient of blood. At this time the case mortality in Germany was about 33 per cent.; there are no statistics from this period available for this country.

In the late eighties the toxicæmic theory began to be discussed. Bouffe de Saint-Blaise observed *post mortem* hepatic lesions, and spoke of a hepatic toxicæmia as being the cause of the disease. Dührssen, no doubt influenced by these considerations, conceived the idea that immediate termination of pregnancy was the proper way to attack a pregnancy toxicæmia, and in 1891 he advocated Caesarean section in all cases, to be performed immediately after the occurrence of the first fit. A few years later he introduced his special method of vaginal Caesarean section. Medical treatment he relegated to a position of unimportance. This treatment caught the fancy of the profession, and had a great vogue not only in Germany but also in the United States of America, for as early as 1911 Petersen was able to collect 530 cases treated by this method in America since Dührssen introduced it twenty years previously; under early surgical intervention upon these lines the mortality in Germany fell from 33 to 18 and 19 per cent.

Other workers, however, continued to practise expectant methods, and wonderfully good results were reported from Russia by Stroganoff as early as 1901. In 1911 he was able to report 600 cases treated by his method in Russia, with a mortality of only 8 per cent. Zweifel about the same time reported a series of 84 cases treated by a modified Stroganoff method with a mortality of only 5.9 per cent. Stroganoff's method was purely expectant, the following being the main points:

1. Isolation of the patient in a darkened, quiet room.
2. Careful attention to the respiratory process:
 - (a) cleaning the mouth, throat, and nose after fits, and

keeping the patient lying on her side; (b) fresh air and, if marked cyanosis, oxygen.

3. Morphine subcutaneously, and chloral per rectum in alternate doses and at stated intervals until fits are controlled, as follows:

0 (zero)	Morphine gr. 1
1 hour	Chloral gr. 30
3 hours	Morphine gr. 1
7 hours	Chloral gr. 30
15 hours	Chloral gr. 22
21 hours	Chloral gr. 22

4. Twenty-five ounces of milk a day, and the same amount of saline per rectum or by the mouth; no other food.

5. Termination of labour when the second stage is advanced.

During the last twenty years the treatment of eclampsia in this country has been, generally speaking, at the mercy of these two antagonistic views—the view represented by Dührssen that active obstetric interference should be practised, and practised early, and the view upheld by Stroganoff that obstetric interference should be avoided until the second stage of labour is advanced, and that the toxicæmic condition should be treated by the simple medical measures just described. Individual clinical observers have emphasized the importance of certain special therapeutic measures, such as saline transfusion, administration of thyroid gland, or of depressants of the circulation, such as veratrine. It is not surprising to find that the prevalence of such divergent views upon the principles which should underlie treatment has produced confusion in the minds not only of practitioners and resident medical officers, but also in the minds of many of the obstetric teachers themselves. The hospital treatment of eclampsia, generally speaking, is to-day in a condition of muddled disorder which is not to our credit. An exception must be made in the case of Dublin, where a uniform plan of treatment has been practised for some ten years, with results of the most encouraging character; but to this matter I shall have to refer again later on.

How serious were the results of this lack of precision in our views as to the principles upon which the treatment of eclampsia should be based was not perhaps generally realized until this summer, when a series of reports on this subject were presented to the British Congress of Obstetrics and Gynaecology at Liverpool. These reports will shortly be published in full in the *Journal of Obstetrics and Gynaecology of the British Empire*. I can only say here that the records of over 2,000 consecutive cases of eclampsia treated in hospital, occurring in the ten years 1912-21, were carefully investigated; 1,800 of them were from England, Scotland, and Wales; 200 from Ireland. The English, Scottish, and Welsh cases together showed a mortality of 24 per cent.; in other words, about 1 in every 4 cases admitted to hospital died. That this mortality rate is capable of great reduction is shown by the cases from Ireland, which showed a mortality of only 10.29 per cent. It is true that the number of cases from Ireland is very small, amounting to only 10 per cent. of the total, but we need not allow this to influence our judgment upon them unduly.

This rather lengthy introduction is intended to emphasize the practical importance of the subject and to point out some of the difficulties. One further preliminary remark I feel bound to make, and that is that we cannot wait any longer for the pathologists. Eclampsia is a disease the causation of which is still unsettled, in the sense that it has not been demonstrated to the general satisfaction. The toxicæmic theory has been very widely, but not universally, accepted, and it must be admitted that it is a hypothesis which is not entirely free from difficulties. I conceive that the time is opportune for an effort to be made to introduce something approaching uniformity into the treatment of this disease, and in order to explore the situation I propose now to submit a short series of propositions to you which cover the main points upon which, in my opinion, treatment should be based.

I. It is easier to prevent eclampsia than to cure it. Prophylaxis is therefore all-important.

The reports to which I have just referred show that in over 80 per cent. of cases of eclampsia premonitory symptoms are present, the commonest of which are albuminuria and oedema. In addition to these there will generally be found headache, disturbances of sight, and epigastric pain, sometimes accompanied by vomiting; more rarely there may be muscular twitchings or attacks of petit mal. Careful

supervision of the patient during pregnancy by her private doctor or at the ante-natal clinic would undoubtedly afford an opportunity for a large proportion of cases of threatened eclampsia to be treated by preventive measures before the onset of fits. It is not certain that all patients with premonitory symptoms will necessarily develop fits, but what I desire to point out is that treatment at this stage may snatch women from the very threshold of this formidable disease.

I cannot give you any figures upon this point, but it is the universal experience that women treated in the premonitory stage very rarely develop fits, and, even if they do so, the disease assumes a mild form. It is reasonable to suppose, therefore, that prophylactic treatment would appreciably reduce both the frequency and the severity of the disease.

I am not unaware of the difficulty not infrequently met with of persuading pregnant women to come up at regular intervals to see their doctor, but the public is becoming gradually enlightened as to the importance of medical supervision during pregnancy, and this difficulty is now much less formidable than it used to be, especially in the case of women bearing their first child. It goes without saying that it is also necessary that doctors and midwives should have a clear idea of the nature of the premonitory symptoms, otherwise even when they occur their grave significance may be overlooked.

Prophylactic treatment essentially is: Bed; fluid diet only, and that mostly water; saline purgatives; diuretics. Progress must be closely watched, the salient points to observe being amount of urine, amount of albumin, the oedema, and, lastly, blood pressure. If progress is not satisfactory, or if relapses occur after temporary improvement, labour should be at once induced without regard to the period of pregnancy or the possibility of survival of the child. Further, I personally do not think it is right to allow a woman who has once been on the verge of eclampsia to carry through to term, and therefore all cases which have developed the symptom complex just described should be induced, although it is preferable, if possible, to defer the induction until the symptoms have disappeared under treatment.

II. *A case of eclampsia is not a case for domiciliary treatment; prompt removal to hospital is the first indication after a fit has occurred.*

It should, I think, be recognized that a case of eclampsia calls for hospital resources as urgently as the most serious surgical operation. The general requirements of the case are:

1. A darkened quiet room.
2. Continuous supervision by at least two trained nurses.
3. Careful attention to the condition of the respiratory passages, as the throat and nasopharynx are apt to become blocked during the convulsive seizures.
4. A well-regulated supply of fresh air, with oxygen in reserve if required.
5. The continuous assistance of a clinical laboratory, and expert medical superintendence always available.

It is clear, I think, that, generally speaking, such requirements can only be met in hospital.

The case of eclampsia which occurs in a remote country district is indeed a tragedy; it can only be met by the provision of proper facilities for transport by ambulance as part of the public health organization of every county.

III. *Cases of eclampsia vary greatly in severity, and a simple classification of cases as mild or severe would greatly facilitate treatment.*

An approximate estimate of the gravity of any case can be readily made in a short time by observation of the following points:

1. The amount of albumin in the urine (catheter).
2. The number and frequency of the fits.
3. The mental condition of the patient.

The reports to which I have previously referred showed that by observation of these points cases can be grouped as "mild" or "severe." The case is a severe one if the urine solidifies on boiling, if the total number of fits exceeds ten, and if there is continuous coma of any degree. The case is a mild one if the amount of albumin is moderate, if the fits are few and infrequent, and if the patient's mind is clear between the fits. The reports further showed that two-fifths of the

cases investigated were severe, and that the mortality of the severe cases was five times as great as those which were regarded as mild, the percentages being 6.5 and 32.4 respectively. This marked difference in the mortality of the two groups is of course a demonstration of the accuracy of the method of classification.

It will be clear that mortality figures from any given centre may be greatly influenced in either direction by an undue proportion of severe cases or of mild cases. The suggestion has been frequently made that the remarkably good results reported by Stroganoff from Russia may be explained by the fact that the disease in that country may assume a milder type than in Great Britain. It is almost impossible to compare results from different centres unless the cases are classified on some plan or other. Further, the value of any particular methods of treatment can be estimated much more accurately if their effects are viewed in the light of the degree of severity of the cases treated. It therefore appears clear that our records should in future always include classification of cases upon some such plan as I have outlined.

IV. *All cases of eclampsia are best treated by the minimum of obstetric interference.*

This should be limited to induction if labour does not come on spontaneously, and termination of the second stage by low forceps when the head has descended to the perineum.

Referring again to the reports previously mentioned we find that cases delivered (a) naturally, (b) by induction, or (c) by low forceps showed a much lower mortality than those delivered by rapid methods such as Caesarean section or accouchement forcé. The greater number of cases of accouchement forcé in the reports were cases in which manual dilatation of the cervix had been carried out in order to expedite delivery; in very few cases was instrumental dilatation practised.

In making this comparison it must not be overlooked that the cases in which a major obstetric operation was deemed necessary may have been of a more severe degree than the others, and would therefore be likely to show a high mortality on that account. This fallacy can be to a great extent eliminated if the cases are first divided into the two groups "mild" and "severe" on the basis which I have just described. I want, therefore, to ask your attention to the following simple figures taken from the reports.

Four hundred and twenty-five cases were analysed and classified into the two groups mentioned above.

Of the mild cases 209 were delivered either (a) naturally, (b) by induction without subsequent assistance, or (c) by low forceps or version; these cases showed a mortality of 5.2 per cent. Further, 51 mild cases were delivered by Caesarean section, with a mortality of 9.8 per cent.; 40 mild cases were delivered by accouchement forcé, with a mortality of 25 per cent.

Of the severe cases 114 were delivered either (a) naturally, (b) by induction without subsequent interference, or (c) by low forceps or version; these cases showed a mortality of 26.3 per cent. Further, 37 severe cases were delivered by Caesarean section, with a mortality of 43.2 per cent.; 10 severe cases were delivered by accouchement forcé, with a mortality of 60 per cent.

I do not think that any words of mine can convey more than these simple figures. Cases treated by the "expectant" obstetric methods showed much the best results. Delivery by rapid dilatation of the cervix is clearly an unjustifiable procedure, and must in future be totally excluded. Cases delivered by Caesarean section, whether mild cases or severe cases, show a mortality nearly double the mortality of those of the same class delivered naturally or by simple obstetric measures.

V. *Simple medical treatment carefully regulated and constantly watched gives the best results.*

In respect of medical treatment our leaders are Stroganoff and Hastings Tweedy. The treatment of Stroganoff I have already outlined, and have remarked upon the remarkable success achieved by it both in his own hands and in the hands of others. Hastings Tweedy's conception is on similar lines, but differs in that he deprives the patient absolutely of all food except water and that he takes great pains to clear the stomach and colon of their contents and to keep them empty. I must not stop to discuss the theoretical consideration upon which Tweedy's treatment of the alimentary canal is based,

or I shall exceed the limits of time allowed me. The forthcoming number of the *Journal of Obstetrics and Gynaecology* will give it fully.

The methods of treatment which will always be associated with these two honoured names have the great virtue of simplicity of conception and of detail, which allows of its being set going without delay in any simply equipped hospital or institution. In my opinion, the crying need of the moment is for the simplification of the medical treatment of this disease and its organization upon a definite plan which can be easily followed.

The London committee which reported to the British congress on 547 cases treated in various London hospitals were greatly struck by the indiscriminate manner in which varied, and sometimes mutually antagonistic, methods of treatment had been often carried out in a single case. Many patients, they say in their report, "were subjected to a multiplicity of drugs, and to a succession of drastic procedures, such as might be expected to reduce a parturient woman in good health almost to the point of death." A certain number of cases were subjected in succession to treatment by purgation, venesection, intravenous saline, morphine, hot packs, and veratrine, besides being delivered by Caesarean section or accouchement forcé; in these cases it appears that excessive treatment may have been largely responsible for any fatal results which occurred.

The Dublin method is based upon the following points:

1. Constant supervision of the patient by a doctor or an experienced nurse, in a quiet darkened room.
2. Complete deprivation of all food except water; to a comatose patient nothing whatever, even water, should be given by the mouth.
3. Stomach lavage to empty that viscus and clear it.
4. Colon lavage for the same purpose, repeated as required to keep the colon empty. Great importance is attached by Dublin to this point; very thorough lavage is practised, several gallons of fluid being run in and out through a long tube, the procedure sometimes occupying as much as an hour and a half.
5. Purgation by salines administered both by stomach and colon.
6. No obstetric procedure whatever until labour is near the end of the second stage.
7. Administration of morphine in total doses of $1\frac{1}{2}$ grain to $1\frac{1}{4}$ grains.

The present master of the Rotunda, Dr. Gibbon Fitzgibbon, has slightly varied this treatment by the omission of the morphine. Treatment on these lines is now generally carried out in Ireland, and the excellent results achieved I have already referred to.

In my opinion the general adoption of the principles of treatment advocated by Stroganoff and Hastings Tweedy would result in an immediate reduction of the mortality of this disease and the consequent saving of many valuable lives. I am not, however, prepared to say that the Dublin method is the last word that can be spoken on the subject. It is without doubt the only treatment required for cases which can be classified as mild. Further clinical inquiry is, however, needed, and will, I believe, be undertaken without delay at the instance of the British Congress of Obstetrics and Gynaecology, to determine whether, taking the Dublin method as the basis of treatment, better results could not be obtained in severe cases by associating with it other procedures. For example, cases not in labour may do better if immediate induction of labour were combined with Dublin treatment; cases associated with high blood pressure may do better if veratrine were combined with the Dublin treatment; cases with numerous fits may do better if some narcotic—not necessarily morphine—were combined with the Dublin treatment.

I have put these propositions in a form which will, I hope, make discussion easy, for I very much want to know how far they will prove acceptable to this Section. Complete unanimity we can never get, and in my opinion we do not want it, for it spells stagnation; but the hopeful feature of the moment is that there now appears to be a prospect of order replacing chaos. Obstetric teachers are working together on this subject and are proceeding upon co-ordinated lines. If a simple logical scheme of treatment could be put forward and backed by something like the united opinion of British and Irish obstetric teachers it would, I am sure, be welcomed by the profession and would be of the greatest public service.

DISCUSSION.

The PRESIDENT said that consultants were constantly being asked what was being done in the treatment of eclampsia. No subject had impressed him as one in charge of hospital beds with such a sense of responsibility as this one. He hoped that much good might result from the combined investigation which was to be carried out.

Dr. CAMPBELL (Belfast) said that, in regard to prophylaxis, no one denied its advantages, but the difficulty was to get women to come for examination. Women must be educated into doing this. The great success of the Dublin treatment justified its continuance. A very close modification could be carried out in a private house. He felt in doubt about those cases whose severity was so great that he was tempted to rupture the membranes—this addition would probably not be approved by Dr. Tweedy—but he thought that the decreased volume of the uterine might give the patient a better chance.

Dr. DOUGLAS (Cupar) agreed with the great importance of prophylaxis. More than thirty-five years had elapsed since his first and only fatal case. From that time he had treated strictly every case of albuminuria, and he had only seen two cases of eclampsia in his practice since. These cases had impressed him with the immense importance of testing the urine in every case and where albumin was present starting treatment at once.

Professor LOUISE McILROY (London) wished to raise three points: (1) the enormous number of cases, (2) the ineffectiveness of treatment, (3) that prevention was the only treatment. That the intestine was to blame could be seen from the success of the Dublin treatment. Epigastric pain might be regarded as a constant sign; this was not due to the stomach but to the liver, probably the result of a *B. coli* infection. Ante-natal beds and out-patient department should be compulsory in every hospital. She considered the treatment of diseased teeth of great importance. She had had no case of eclampsia among those who had received ante-natal treatment. She was very keen on injections into the bowel of sodium bicarbonate by means of a douche can fitted with rectal nozzle, the fluid being delivered very slowly. She considered that induction of labour was a very dangerous thing, as an enormous quantity of toxic substances was going to be poured into the blood stream. She condemned drug treatment whole-heartedly.

Dr. LATHORN SMITH (London) thought that every case of eclampsia could be saved by prevention. He had not seen a fatal case for thirty years. Women would not come to their doctor unless the doctors made them come. If the urine were carefully examined and treatment commenced without delay there should be no difficulty in bringing a patient through without convulsions. He considered that sodium bicarbonate was the most valuable drug without the slightest doubt. Piles and vomiting might be ascribed to the same common cause—intestinal intoxication. He recommended the cutting off of all nitrogenous food and he emphasized very strongly the importance of making pregnant women drink plain water in sufficient quantity. When convulsions had come on he considered morphine was then the most valuable drug. Morphine did not suppress the renal function, as used to be taught—it aided it. He would like to see the use of chloral prohibited. He was against the induction of labour as it might give rise to considerable shock; on the contrary, he would advocate Caesarean section.

Dr. LAURIE (Greenock) said that undoubtedly cases with considerable albuminuria responded well to treatment, but many women refused to come into hospital. He had had five cases with complete coma, suppression of urine, almost constant convulsions, total blindness, and anasarca. He had done Caesarean section and all had recovered. Operation in such cases appeared to be the only thing left to do. He said that he was a great believer in butter milk and large saline enemata for patients with albuminuria.

Dr. RUSSELL ANDREWS (London) quoted the wise old physician who said, "Let your patients die if they must, but don't kill them." He was delighted with Dr. Eden's advocacy of simple methods. These cases had been overtreated. He was certain that morphine had killed many patients. Injections of saline had been overdone to an absurd degree—at post-mortem examination all the serous cavities had been

found full of fluid. Croton oil had been found in the bronchi. The combined investigation hold out very great hope for the future. A proper classification of cases would avoid the application of all treatments to one case.

Dr. BALLANTYNE (Edinburgh) made three points: (1) eclampsia was intractable but preventable; (2) as regards the child the outlook in eclampsia was bad; (3) preventive treatment was amazingly successful, but it was of necessity very difficult to state results.

Professor MUNRO KERR (Glasgow) stated that he had been informed that treatment in France was on the same lines as advocated by Dr. Eden. He could not agree that prognosis should be based on the quantity of albumin; the most toxic cases often had only very slight albuminuria. He still considered that in certain cases Caesarean section was the only resource, but the difficulty was to select these cases. He thought there was too much operating at present.

Mr. FARQUHAR MURRAY (Newcastle) strongly endorsed all that had been said in regard to prophylaxis, especially in connexion with the teeth and the intestine. Proper care of the bowels would reduce these cases to less alarming proportions. He did not give the patients at his clinic a list of warning signs, but instructed them to report at once if they felt a little out of sorts: he regarded this as good indication as the urine for pointing the need for careful supervision.

Dr. LEWIS asked what precautions might be taken to give advice on this subject to midwives. The only cases he had seen during the last four or five years were cases attended by midwives. He did not think they tested the urine nor appreciated fully the importance of the routine examination. They should be taught to do so.

Dr. EDEN, in closing the discussion, agreed that midwives needed better instruction and should work in closer co-operation with the doctor. *Post partum* fits should be treated by the Dublin method just the same as the *ante-partum* cases. As regards intestinal intoxication he found on looking through the figures that in the two war years, when the food shortage was most acutely felt, the ratio of eclampsias fell considerably. Had the food shortage anything to do with this? In regard to Caesarean section he felt that the easiest way was not always the safest way. But his mind was quite open on the subject, and when Professor Munro Kerr had told him in what cases to do Caesarean section he would do it. He had purposely omitted references to the effect of eclampsia on the child, for the sake of brevity.

THE TREATMENT OF GYNAECOLOGICAL CONDITIONS BY X RAYS AND RADIUM.

BY

ROBERT KNOX, M.D. EDIN.,

Director of the Electrical and Radiotherapeutic Department, Cancer Hospital; Honorary Radiologist, King's College Hospital.

IN introducing the subject for discussion it is well to state at the outset that so far as effects are concerned either x rays or radium may be useful, and that in certain cases the use of the two agents in combination is an advantage.

In dealing with the general question of radiation treatment it will simplify the matter if we assume that the potency of the radiation employed is the important point, and that it makes very little difference whether the radiation is produced by an x-ray apparatus or a quantity of radium. It is essential to ensure that the area treated gets a dose of sufficient intensity to produce the changes necessary for the cure or relief of the condition. The technique of the application is therefore an important step in the treatment. The estimation of the dose is another most important step, and that necessitates expert knowledge of apparatus, physics, and the biological reaction of the tissues.

The dose is determined by physical means; the measurement of the radiation from an x-ray tube or from a quantity of radium is now a fairly precise procedure, and one upon which absolute reliance may be placed. Elaborate instruments are used for the purpose, both in the laboratory and in the

treatment rooms. Thus it is possible to calibrate the x-ray tubes and the radium applicator and determine what dose is given from each in a given time.

Later methods indicate that if the radiations could be described in relation to its wave length it would simplify dosage very considerably. For instance, in the electromagnetic spectrum about sixteen octaves are occupied by the x rays and the gamma rays of radium. Of these so far only three or four octaves have been used. The voltages required to produce the available wave lengths vary enormously. The x-ray value used for the intensive treatment of uterine conditions runs in the region of 200,000 to 250,000 volts, while the most penetrating gamma ray from radium approximates to 1,000,000 or more. So for practical purposes if x rays and radium rays are available, a range of wave lengths from 200,000 to 1,000,000 volts is available for the treatment of the conditions met with in gynaecological practice.

In deep therapy it is necessary to know exactly what percentage of a beam of rays will reach a certain depth, and what percentage of the arriving beam will be absorbed by the tissues. The determination of this factor is a purely physical problem, and the experimental results are readily obtained. Precise instruments again help us in the examination.

The third step is to determine what takes place when the radiation reaches the tissues, and what the effects upon the metabolism of the cells may be after absorption. It is known that secondary rays are produced by the primary ray acting upon the tissues, and the scattering of the rays is an added factor to which great importance must be given.¹ These have a marked effect upon cellular structures, and the degrees of susceptibility of varying cells have been worked out as a result of experience in treatment. So on the one hand we have the wave length of the radiation as a physical factor capable of precise measurement, and on the other the varying susceptibility of the cellular structure of the tissues. Future measurements of effect may be worked out on these two main lines, and it may be possible to select the wave lengths which will have the maximum effect upon a particular type of cell of which the main part of a tumour consists.

In the treatment of fibromyoma, for example, the action of the rays appears to be exerted primarily on the ovary and its blood supply, suppression of function leading to atrophy of the structure and cessation of the menstrual haemorrhage. The latter is the most troublesome symptom arising from fibromyoma, and the improvement of the patient's health may in fact be attributed to its cessation. The atrophy of the ovaries is, however, accompanied in a number of cases by a diminution in the size of the tumour. It is reasonable to assume that an action is exercised upon the tumour itself. It is therefore advisable, when treating the ovarian areas, also to include the tumour. The tube is arranged in treating each area so that the beam of rays may be focused upon a given spot. If each ovary gets the maximum effect from each of those ports of entry on the side on which it lies, the tumour also receives a very large proportion of the radiations passing through it, and changes occur in its structure.

Whatever the action may be and upon whatever structure the rays act most, there is no doubt whatever that in the treatment of those conditions many marked beneficial results can be obtained by carefully applied courses of radiations.

Biological Reaction.

The biological response to radiations has been worked out in several centres, notably in Germany, by Seitz and Wintz, and by Kronig and Freidrich. It is obtained by multiplying the physical dose by the sensitive coefficient of the tissue affected. It depends upon the sensitiveness of the absorbing medium, and according to a number of observers it varies with different histological structures. Muscle reacts differently from skin, carcinoma cells differently from ovarian cells, and these again differently from the cells of a sarcoma. In 1916 the writer published details of observations on the response of enlarged glands to definite doses of radiation. The results then given conform in the main with the observations of workers in Germany.

To obtain a uniform method of dosage Seitz and Wintz introduced the term "unit skin dose," together with a biological system of measurement. This unit skin dose is obtained under definite physical conditions, and they state that the normal skin can be used quite well as a biological

test object. By unit skin dose (U.S.D.) Seitz and Wintz mean that amount of radiation which after eight days will cause a slight erythema, and after four weeks a slight tanning of the skin. On the basis of this definition, which they have placed at the arbitrary figure of 100, they have determined other doses, constituting their biological system of measurement. The figures quoted are from their work, and in all of them the unit skin dose forms the basis. The following figures are given to illustrate the points:

(1) Unit skin dose	100 % of U.S.D.
(2) Castration dose	35 % of U.S.D.
(3) Sarcoma dose	60-70 % of U.S.D.
(4) Carcinoma dose	90-110 % of U.S.D.
(5) Intestinal dose	135 % of U.S.D.
(6) Muscle dose	180 % of U.S.D.
(7) Tuberculosis dose	50 % of U.S.D.

It is assumed in these figures that, if the uniform skin dose is taken as 100, 35 per cent. of such a dose reaching the ovaries will in time induce amenorrhoea of a permanent character; 60 to 70 per cent. reaching a tumour will lead to changes in it, if it is chiefly composed of sarcomatous elements; 90 to 110 per cent. will induce similar changes in a carcinoma; 135 per cent. is the dose which will injure the bowel; 180 per cent. the muscles; and 50 per cent. of the erythema dose will react favourably upon tuberculous conditions.

It would be well not to place too implicit faith in the accuracy of these observations. The response will be by no means invariable, because there are other factors, of which no notice is taken, which will permanently change the character of the response—for example, a carcinoma will react at one period of its life history while at a later it may refuse to respond at all, and so on.

As indicated, it may be well to resort to radium instead of x rays when the type of tumour requiring treatment is one which indicates a value in wave lengths well beyond the limit of the x radiations at our command. It is for this reason that the combined use of the two agents is advocated in a number of cases of deep-seated carcinoma. Radium can be applied to the interior of hollow organs, and the dose administered with a precision that is almost impossible under present x-ray conditions.

It is most important that due consideration should be given to the technique to be adopted for the treatment of one or other of the graver forms of pelvic disease. It is clear that if we could select a particular wave length for use, the apparatus which in the case of x rays supplies the high tension current should be so graded that any voltage within reasonable limits could be obtained. In the treatment of fibromyoma and carcinoma of the uterus the technique has been clearly worked out in the German and other schools, and is now being generally adopted in this country. X-ray tubes capable of long runs at high voltages are now procurable, and it is even possible to administer what is known as the sterilization or the cancer dose at one sitting. It may be pointed out that this is not invariably so, for it is frequently necessary to repeat the dose after an interval of several weeks. Whatever the accuracy of the statement may be it indicates an advance, and an attempt to standardize technique.

The important point is that when the correct dose has been given for the condition requiring treatment changes are set in action which in a percentage of cases yield effects which are curative. The old and better known techniques do not aim at such a rapid effect; these have in a number of cases given quite satisfactory results, and are still in the main adhered to. It is probable, however, that in the future the tendency will be to increase the initial dose and depend more upon it for the attainment of results. It is also probable that a modification of the newer technique may be advisable. These remarks apply mainly to the x-ray technique. Radium is being used more frequently than in the past, and it is more than likely that a great improvement in the technical use of radium will lead to an improvement in the results.

The radium technique is very simple. It consists of the use of radium salts in small tubes; filtration is employed according to the effect it is desired to obtain. Metal filters of silver, lead, brass, or platinum are used. Radium is most conveniently used for the deep-seated lesions, when the tubes can be introduced into the interior of an organ, or when the tumour is within reach, when radium tubes may be inserted into the substance of the growth:

The treatment of a case of carcinoma of the uterus calls for expert knowledge, and a careful operation under an anaesthetic is often required for its execution. Care may be taken to protect the surrounding tissues from damage by overexposure. The use of radium is advocated for uterine carcinomata after the method described. The best results are obtained by the combined treatment. When radium is used the field of action is somewhat localized, the intensity diminishing in inverse ratio to the square of the distance of the object from the source of the radiation. At 3 cm. of tissue the effect is very small. X rays may be administered from several aspects of the periphery, centring the beam upon the tumour. In this way extensions of the malignant disease by way of the lymphatics may be prevented. It is therefore logical to assume that in the combined attack we are doing the best possible for the patient.

The x rays can be applied through large areas and from several entrances; in this way a large dose may be concentrated on a lesion in a deep region of the body. An example of malignant disease of a pelvic organ may be taken to explain how the dose is administered. If the growth is situated in the mid region between the anterior and posterior walls of the pelvis it can be approached from four aspects, thus:...

Four tumour deliver ... dose. At the sent of the 80 per cent.; C and D each 120 per cent.

Using a beam of radiation of which 40 per cent. will be absorbed by the tumour, then from the anterior and the posterior aspects 80 per cent. of the U.S.D. will be given that is not enough, so from each of the lateral aspects a dose is given of which 20 per cent. will be absorbed by the tumour. We now have $40 + 40 + 20 + 20 = 120$ per cent. of the U.S.D. that is, just 20 per cent. over the estimate of 100 per cent. the lethal dose.

The x rays cover a large area and so enable us to treat not only the tumour but its whole area of lymphatic drainage. Experience has taught that in all cases of cancer it is essential that the lymphatic field should be treated to as heavy a dose as the primary tumour receives. In this way it is hoped that metastasis will be prevented. Should cancer cells exist in a region some distance from the primary growth they may be removed either by operation or by radiation treatment, a recurrence of the disease at a later date is to be prevented. The aim of operative and radiation treatment has been to prevent such an occurrence; in consequence of this operative measures have become more extensive in the area operated upon; similarly, the tendency is to increase the field of irradiation and also the intensity of the radiation.

It is probable that in the operative results improvement in the statistics may be attributed in part to the better appreciation of the extensive field of invasion and its complete removal. Radiation results have also improved since the larger dosage and wider fields of irradiation have been employed. Statistics whose object is to prove the value of radiation methods are therefore very difficult, and it may be that a long time must elapse before any definite conclusion can be drawn from them. A comparison of statistics given by operative and radiation figures is also very fallacious, because of the difficulties associated with the facts submitted. Attempts are made to compare statistics on operative and radiative cases chiefly for the purpose of proving that the latter give

good results as, if not better than, the operative; impartial critics are inclined to favour the operative, and if this be so it is perhaps only reasonable to proceed a little further and consider the other points of comparison between the methods.

The newer methods, and particularly that known as the "Erlangen" method, involve a considerable strain upon the patient; briefly, the whole treatment occupies in the first instance seven or eight hours of continuous radiation. In the Erlangen technique the radiation treatment is preceded by a prolonged ionization of the local tumour. This constitutes the first treatment; it is followed at an interval of about six weeks by another long dose, and at a still later period by the third series of irradiations. In all a period of three months will elapse before the treatment is completed. It is possible that with improvements in apparatus and increased output the time required for the dosage will be materially shortened; when it is possible to reduce the time of irradiation to about two hours the strain upon the patient will be lessened.

When compared with the operative method it is not nearly so rapid in the attainment of the result—that is, the removal of the tumour. The drain on the system is not so sudden, but it may be more severe, and any depreciation in the blood constituents may be a serious factor in the progress of the cure.

The next question is whether it is more complete in its results. Is it possible to remove not only the primary growth but all possible extensions of it? In other words, can the x-ray method compare with the surgical so far as complete removal is concerned? The answer must be in the negative. Statistics of Wertheim's operation are available; the percentage of persons cured after, say, three years varies greatly with the operation and the stage at which the disease was operated upon. The Roentgen Wertheim, as it has been called, has not been in use long enough for reliable figures to be forthcoming, but the figures which have been published on x-ray treatment in carcinoma of the cervix on the older lines do not encourage us to support the claims in favour of x rays against those of surgery.

Our own experience has been such that in all cases which are suitable for surgery we strongly recommend it. It is well, however, to insist upon prophylactic x-ray or radium treatment, because it is felt that combined treatment is best for the patient. When the condition is considered to be inoperable there is no choice. Radiations should be employed in all cases; then it becomes a question of the best technique to employ. Radium and x rays in combination are placed next to surgery in the treatment of all malignant diseases of the pelvic organs. Radium is used internally whenever possible, and x rays from the periphery inwards to a central point, which is somewhere near the centre of the tumour. Tubes containing radium or its emanations with suitable filters are introduced into the canal, and other tubes or needles are pushed into the tumour mass. Radium used in this way has a very limited but concentrated action. Care should be taken to place the tubes within 3 cm. of each other, and the whole of the tumour should be pierced by these needles, the aim being to get a maximum and uniform irradiation of the whole of the tumour mass. Careful packing around the tubes is required to prevent the adjoining structures from receiving damage.

The lymphatic field, whose centre is the tumour mass, must now be very thoroughly irradiated from the periphery of the body towards the centre whose area includes the tumour. As many as six ports of entry from the anterior aspect are used. Similarly several areas from the posterior aspect may be used. The aim here is to thoroughly saturate the tumour with radiations and to induce changes which will destroy any cancer cells, or at least render them inert. Very large doses may be required to do this thoroughly; it demands very careful technique.

In carcinoma of the body of the uterus operation is the first choice; in carcinoma arising in the cervix the claims of radium must be seriously considered. The use of x rays in this connexion is not certain enough to warrant the consideration of x rays in preference to radium. With a sufficient quantity of radium the dose could be shortened to endurable limits. The x rays are used from the periphery. This, in our opinion, is the best routine to follow, and offers in suitable cases a prospect almost as good as does the complete operation.

Pre-operative treatment by x rays is not advocated in cases which are going to be operated upon (unless for some other reason the operation is delayed), because if x rays are to be useful the dosage must be a maximum one, and the area covered must include all possible lines of extension from the primary lesion. The administration of the cancer dose involves a large surface of irradiation, and serious constitutional symptoms may arise; these if severe and supervening upon operation might jeopardize life, and at a later stage the effect on the blood might so weaken the patient's power of resistance that convalescence from the operation would be retarded.

The advances in technique have changed the view regarding pre-operative treatment; it is indicated that the choice must be made as early as possible between the operative and the radiation treatment.

It would be well in considering the relative values of x rays and radium to understand clearly that no antagonism exists; the one can be and frequently is supplementary to the other, the controlling factor being the case with which one or the other can be used. It may be admitted that if an equal dose from either is administered the effect upon the tissues will be the same. The difficulty with radium is to get a sufficiently large quantity to ensure an equal distribution of the rays over a large tumour. A large number of tubes may be required to thoroughly irradiate a tumour mass; and it may be necessary in such cases to perform an extensive operation in order to get the tubes in position. It might be possible in such cases to saturate the tissues thoroughly by the use of x rays, and with the shorter wave lengths coming into use it will be possible to do this, even when a tumour is situated in the interior of the body.

Another factor of some importance is the response of the tissues to the radiation. Some may only require a large quantity of relatively long wave lengths, while in others the shortest wave length of the gamma rays of radium may be more suitable.

The critical test of the value of radiations in practice will be the results obtained in the treatment of malignant disease. All forms of malignancy will come under consideration, and differences of opinion will find expression according to the type of disease, the stage at which it is treated, and the technique employed. So far the evidence is in favour of a combined attack by the surgeon and the radiologist in malignant disease; the advantage of collaboration is well recognized. In non-malignant disease of the pelvic organs the same observation holds with even more force.

The final word on the value of the treatment of uterine fibroids by x rays will rest largely with the gynaecologist, but the radiologist who pays attention to the clinical aspect of the case and remains in touch with the patient will also attain a proficiency in the estimation of particular values. The medical man in direct charge of the patient is, however, frequently as competent to judge as either the radiologist or the gynaecologist, and he is indeed the best judge of the after-results of all treatment because of his more intimate association with the patient.

All cases of fibroid enlargement of the uterus or of malignant disease where radiation treatment is proposed should be examined by a gynaecologist, who will report on the condition and express an opinion of the suitability of the case for this treatment. In this way a judicious selection of cases will be ensured, and the value of the method be estimated. The converse also holds good: no case should be treated by radiations by anyone who is not an expert radiologist. The time is fast approaching when gynaecologists will adopt x-ray treatment as a valuable adjunct, and it is imperative that they should take steps to become thoroughly familiar with the intricate subject of radiotherapy. Personally I have treated all cases in close touch with a gynaecologist, and it has also been my practice to send back to the gynaecologist all cases on completion of treatment for a final opinion; and also, for further advice, all cases which have failed to respond.

An illustration of the value of such collaboration is the case of a patient who was sent for x-ray treatment of menorrhagia which was supposed to be due to the presence of a fibroid. My request for an expert gynaecologist's opinion was refused by the patient, so I reluctantly undertook to give her a number of exposures. The result was not satisfactory, and, as I suspected from her symptoms that I was dealing with a mucous

polyps. I insisted upon the expert opinion. The patient was examined, the opinion confirmed, and surgical treatment relieved the condition.

On another occasion, symptoms having arisen which called for an examination of the blood, the opinion of the clinical pathologist led to the services of a physician being called in.

A lady of middle age had suffered from exophthalmic goitre, and as a result of treatment at a health resort had improved, but had not quite recovered. Later she experienced severe floodings and consulted a gynaecologist, who treated her for some time; the haemorrhage, however, became more severe, and she was sent for x-ray treatment. The case was a complicated one to deal with, but under the circumstances I felt justified in treating her. The response to treatment was good at first, but in the middle period between the doses she began to show alarming symptoms. Before giving her a heavy dose which was expected to effect a cure of the haemorrhage I asked for a full blood count. The white cells were very low in number, so I determined to suspend x-ray treatment for a time and handed her over to a physician. A course of tonics combined with rest proved very successful—the blood count showed a marked improvement. The haemorrhage ceased for several months, and the general health improved greatly. When last communicated with the patient was in perfect health.

The lesson taught by this case is very important. In serious cases it is always well to control treatment by blood counts at regular intervals. Serious accidents will thus be avoided, and the radiologist will have a valuable guide for modification of technique. A drop in the total number of white cells is always an indication that treatment must be suspended or very cautiously continued. It will also be a guide for the actual dosage. Had I persisted in the case quoted and given the very large dose I had intended I have no doubt that I should soon have reduced the white cells to the danger point and would undoubtedly have seriously injured the patient. The need for complete and frequent blood examinations is much more imperative since the very intensive dosage has been adopted.

Contraindications to Treatment by X Rays (or Radium).

There are certain conditions which if coexistent are direct contraindications to radiation treatment—in fibromyoma, for example.

1. It is obvious that if a large portion of the fibroid has become converted into calcareous matter, and if the tumour is of large size, x rays can have no beneficial effect. In doubtful cases a radiographic examination will reveal the extent of the degenerative change.

2. Most forms of degeneration should be excluded before x rays are administered, though, if not very extensive, the treatment may be tried.

3. Malignant disease of the uterus calls for very careful consideration. Operative measures should be discussed. If it is impossible to remove the tumour, then there is no objection to a combined attack on the disease by x rays and radium. Very careful application of radium tubes is necessary, and for this a general anaesthetic is indicated.

4. Infective conditions of the uterus complicating fibroids.

5. Suppurative salpingitis or pelvic peritonitis.

6. Inflammatory conditions of other organs in the vicinity—namely, appendicitis, cystitis, etc.—should be dealt with before attempting to treat the fibroid.

7. Submucous pedunculated fibroids.

Advantages and Disadvantages of X-ray Treatment.

The advantages are:

1. The treatment is quite painless, and any ill effects are quite temporary.

2. The patient can live her ordinary life, merely arranging for one or two days of rest after each treatment.

3. No elaborate preparations are required.

4. The resulting menopause is not usually attended by such severe nervous disturbances as those following operation.

5. In patients whose general health is much impaired the recovery is very rapid when the haemorrhage has been arrested; moreover, the shock so often inseparable from hysterectomy is entirely obviated.

The disadvantages are:

1. It takes a considerable time to effect a result; treatments may have to be given at intervals for several

months. The use of the more penetrating radiation and the larger dose indicate that the time taken to produce the effect will be greatly shortened. If the correct dose is given the changes may be induced by one application.

2. The treatment is not invariably successful.

3. The tumour, though as a rule much reduced in size, does not entirely disappear.

4. Treatment may cause unfavourable changes in the blood.

Dangers of X-ray Treatment.

Indiscriminate treatment by x rays is very dangerous. The skin may be seriously damaged and severe burns induced. In one case—that of a patient who was treated for a supposed malignant growth of the pancreas for over a year—there was when I saw her a large, fairly deep x-ray ulcer, and around it a large area of inflammatory reaction. I watched the ulcer for over a year and only used palliative applications. In about eighteen months it healed. An accident such as this is avoidable and should never occur in cases where the technique is intelligently carried on.

The dangers incidental to the action of the radiation on the deeply situated organs and tissues have been referred to in the consideration of the biological factor. The blood may be prejudicially affected by the larger dose now in use. It must be carefully watched during the periods between the doses, and any severe fall in the number of the white cells is an indication for the suspension of treatment.

Overdosage to the deeper structures may at a later date give rise to serious disturbance of function. It must not be forgotten that there are such occurrences as late manifestations of x-ray effects; these may take on a variety of forms, and may show after an interval of many months or even years.

DISCUSSION.

The PRESIDENT wished to thank Dr. Knox for a very sane exposition of the subject. Too often methods of treatment were spoken of in superlative terms, and failures were relegated to a small footnote. He thought that the profession should be on its guard in accepting so-called evidence of cure in cases of malignant disease; such cases should be subjected to the most rigid tests. Quite extraordinary results had occurred in cases of what was apparently malignant disease completely clearing up after simple curettage. Similarly, in fibroids some cases made remarkable steps towards recovery by themselves, so that it was necessary for any form of treatment to be subjected to searching tests before definite claims were put forward for it.

Dr. KATHARINE CHAPMAN (Glasgow) asked for a more full account of the contraindications to radiation treatment. For instance, it was said that submucous fibroids were generally regarded as unsuitable for this treatment. Again, it was said that x rays caused abdominal adhesions, but she had never yet found satisfactory evidence that they were not present before treatment was applied. She even thought that x rays might be applied for the treatment of adhesions, and cited a case in support of this view. She could not explain why patients improved so markedly when they were being sterilized. She had had cases of young girls suffering from pain, sickness, and haemorrhage who had shown marked improvement after the application of x rays.

Mr. GREIG ROWNTREE (London) said that he would feel somewhat diffident in addressing such an audience as a general surgeon but for the fact that at the Cancer Hospital many cases of carcinoma of the cervix were admitted, most of them inoperable. Carcinoma of the cervix could give a very useful test of the efficacy of x-ray and radium treatment, as the local growth usually killed the patient before there was time for the formation of metastases. For a long time he had been disappointed with the treatment, but his results had improved greatly during the past year as he had changed his method. He now always gave an anaesthetic and buried the radium in the substance of the tumour. With this method the local condition very greatly improved. He had often employed far larger doses than Dr. Knox had recommended, as the cases appeared to be so hopeless. In answer to questions, Mr. Rowntree said that he had not met with any case of vesico-vaginal fistula caused by burying radium, but he had had one case of fatal haemorrhage occurring on the

day after the patient left the hospital, and he now advised ligation of the internal iliac arteries as a precaution against such accidents in the future.

Professor MUNRO KERR (Glasgow) wished to express his high appreciation of the manner in which Dr. Knox had presented his subject. Gynaecological surgeons owed a deep debt of gratitude to radiologists for the most valuable assistance they had given them in dealing with many affections which previously could not be so simply or so satisfactorily treated. As regards chronic metritis and fibrosis uteri in women approaching the menopause there was no doubt that x-rays was a most valuable treatment. In a large number of cases so treated the results had been excellent. Some cases of extensive pelvic inflammation which were unsuitable for operation had been most satisfactorily treated in the electrical department of the Glasgow Royal Infirmary. He had had a few cases under his care of extensive tuberculous inflammation of the pelvis where on opening the abdomen operation was not considered advisable as adhesions of bowel were too extensive, and the danger of injuring the bowel almost certain—a very serious complication in such cases, which had proved very satisfactory when submitted to x-ray treatment. When they came to fibromyomata there was the danger that x-rays might be employed too freely, and as a matter of fact as far as pigmentation could prove this was the case. He thought that they had not yet fully exploited surgery; hysterectomy was too common; myomectomy had not yet attained its proper position. He felt that greater consideration should be given to this operation. The uterine cavity might be opened and an organ which appeared hopelessly diseased might even be restored to full function when hysterectomy appeared to be the only apparent treatment. Myomectomy should certainly receive more consideration than was being given to it at present. With regard to x-rays, radium, etc., for carcinoma of the cervix Professor Munro Kerr had no fixed convictions. He employed radium prior to operation when it was procurable, and he believed that this treatment was of great value preparatory to hysterectomy, and it seemed to him that Erlangen treatment afterwards, say for three weeks, should be of great advantage, but so far he had employed this in only one case.

Dr. ARTHUR BURROWS (Manchester) was very pleased to hear that Mr. Rowntree was getting better results from burying radium. In regard to the certain diagnosis of malignancy, he said that in Manchester sections were taken from all patients as a matter of routine. A certain number of chronic inflammations gave every indication of malignancy and diagnosis was sometimes exceedingly difficult. He did not wish to say much about carcinoma of the cervix. He thought that at present they were stationary, and progress would not be made until the radiologist began to treat operable cases. This he supposed must be a gradual process, but surgeons should draw the line of operability tighter, and those surgeons who did draw the line were the most pleased with the results of radiation treatment. The Erlangen results were nearly all obtained by the treatment of operable cases. The hopelessness of treating some cases by any means must be admitted. With a sufficient quantity of radium the outside of the pelvis could be bombarded as well as the inside. He considered that a combination of the two types of radiation was difficult and complicated, as the two types of rays had their lethal doses in different parts of the scale; hence present methods were markedly empirical. In regard to fibroids, x-ray treatment was not sufficiently certain to displace surgical methods, which were, on the whole, very satisfactory. He agreed with Dr. Knox that the effects of radium were often so good that it was difficult to conceive that removal of the ovaries could have done the same. He thought that the treatment of fibroids by radiation should be reserved for special cases: (1) when the general health would not permit of surgical interference; (2) for the relief of symptoms preparatory to operation; (3) where for business reasons it was not possible for the patient to spare the time to undergo operation and the subsequent period of convalescence. Dr. Burrows then went on to discuss some of the less talked about subjects. He had obtained one good result himself in a case of chorion epithelioma. In regard to epithelioma of the vulva, he advised operation in early cases. His reasons were that treatment by external tubes and plates with the quantities of radium available was useless, while the best methods—namely, the use of unscreened emanation tubes or thinly screened tubes (that is, beta radiation)—caused an

excessive reaction accompanied by considerable sepsis; hence the patient had to remain in hospital to receive proper nursing attention. In these cases he now applied diathermy first over the surface of the growth and then applied tubes—this procedure seemed to diminish pain. In some hopeless cases results were brilliant, but for operable cases operation was certainly far less painful. In the treatment of menorrhagia those cases which had already presented no difficulties, but in the young women the matter was much more difficult, owing to the alleged action of the rays on the ovaries; he was always reluctant to treat the latter type of case. He advised first curettage; hysterectomy was admittedly an abject confession of failure. If curettage failed to check the bleeding then exposure to a half-dose system, say 50 mg. in twenty-four hours, might prove successful, but it might fail. He did not think that the effect could all be ovarian as a number of cases had been quoted of patients who had borne children subsequent to the treatment. He had treated a few cases of bad dysmenorrhoea in a similar manner successfully.

Dr. FARQUHAR MURRAY (Newcastle) thought Dr. Knox's paper was scrupulously fair. He laid emphasis on the importance of full co-operation between the radiologist, the gynaecologist, and the pathologist. His experience of radium in cancer of the cervix had been most encouraging. Inoperable cases showed local improvement, and microscopic examination made in cases subsequently treated by the radical operation showed marked fibrosis of the cervix with degeneration and fibrosis of the cancer cells. This suggested the advisability of a routine pre- and post-operative radiation of the lymphatic field. He quoted two cases of complications following soon after radium treatment; one had a temporary hydronephrosis and the other intractable scintica. He did not favour the x-ray treatment of fibroids. The great drawback to radiation treatment generally was that it was so very expensive.

Professor LOUISE McILROY (London) asked whether Dr. Knox had any experience of x-ray treatment for menopause symptoms. As to fibroids, she was certain that they were the signs of a toxæmia; not infrequently the symptoms were not cured when the fibroids had been removed. She thought that in cancer post-operative radiation was the ideal rather than pre-operative radiation. Radiologists had not been given a fair chance as they had only been allowed to treat inoperable cases.

Dr. H. E. GAMLEN (Newcastle) said that during the last fifteen years he had had a large experience in the treatment by x-rays of diseases of the female generative organs, and by these methods he had attained successes which generally proved to be only temporary. Two years ago he had begun the treatment of some of these ailments by means of radium, using two tubes containing 100 mg. The method adopted was generally the laying of these tubes over the seat of the disease, duly filtered and protected, and some startling results ensued, and though afterwards he had found that some of these results were only temporary, yet in some cases he had been able to make operable malignant diseases of the uterus which had previously been declared inoperable. Several successful operations had been performed as a result. Stimulated by the successes obtained by Dr. Arthur Burrows of Manchester, he obtained a further supply of radium amounting to 200 mg. of radium bromide made into seven needles. By means of these the growth and surrounding tissues were freely treated, and at the same time the protected tubes of radium were inserted into the uterus, with encouraging results. On reviewing the results obtained he decided to go a step further, and in addition to treating uterine cases with large doses of radium he had given the whole areas affected deep therapy by the Erlangen method. He had found that he was able somewhat to reduce the dosage with less risk of giving the intervening healthy organs an excessive dose of deep therapy as he now finished the deep therapy within forty-eight hours, during which time the radium was in position in the uterus and surrounding areas. He was very hopeful that in some of these cases a knock-out blow would be given to the disease in question. In the later cases he had always ascertained the exact depth of the disease from the various fixed the its C had been hopelessly inoperable, but the present results had been encouraging; many of the patients after treatment

had undergone operation in an attempt to eradicate the disease. Owing to the encouraging results they had obtained in chronic malignant disease of these organs, and the experience gained in the use of radium and deep therapy, he considered that the time had come when the surgeons should give them an opportunity of testing this treatment upon earlier cases, as he believed that if thoroughly carried out this treatment would finally give better results than surgery alone. To obtain the best results it was necessary that the work should be done in conjunction with the gynaecologist.

Dr. Knox, in the course of his reply, said that he thoroughly agreed with the remarks of the President as to the absolute necessity of a high standard of efficiency in the diagnosis of malignant disease. He himself always tried to get a corroborative report in every case. He also relied on the nature of the response obtained by the radiations. He had at present under treatment a case which confirmed this: a patient with enlarged cervical glands with a definite diagnosis of malignancy gave such a remarkable response to treatment that he had questioned the diagnosis. He had obtained the slides upon which the pathologist had reported, and these, when submitted to several pathologists, were regarded by them as non-malignant and probably inflammatory. Yet on two other occasions this patient had returned within the last year, and on each occasion the response to several doses had been remarkable. In regard to practically all cases of fibroids and malignant disease 99 per cent. of the cases which he had treated had been sent to him by gynaecologists. He always acted in collaboration with his colleagues, and he generally left the question for and against treatment by radiation to be decided by them. He felt certain that team work was essential in all work of this kind; included in the team should be a skilled pathologist. By such means they might gain reliable information in regard to values. Then as to the treatment of fibroids: Submucous fibroids might do well; he could see no reason why they should not, providing they were not protruding through the cervical canal and pedunculated. He had had no experience in the treatment of pelvic adhesions. It might be that if a very large tumour were rapidly reduced in size adhesions might form if there was overdosage and peritonitis resulted therefrom. Speaking generally, radiations caused absorption of fibrous tissue in superficial lesions, so he could see no reason why it should not act as well in adhesions complicating fibroids. The good effects obtained during sterilization he had found constant in his cases; they were very noticeable. Dr. Knox said that he had only treated very few cases of haemorrhage in young girls. He thought the treatment would have to be done very carefully, shielding the ovaries and applying the dosage skilfully. He had seen fistulae occur after radium treatment, but he did not think that they were necessarily the direct result of the treatment. He thought that tying the internal iliacs was sometimes done with good results. In tuberculous disease of the abdomen he had not had much experience; but he had seen some encouraging results from x ray treatment, particularly in cases showing enlarged glands. He agreed with Dr. Burrows's observations. He was with the surgeon in the matter of fibroids. He was constantly placing surgery in the first place. In cancer operation was the first choice whenever possible, to be followed by intensive and extensive radiation either by x rays or by radium. He did not advocate pre-operative radiation as a very wide area would have to be involved, and that might expose the patient to further risk of spread. He was in agreement with Dr. Burrows about the treatment of epithelioma of the vulva. Certainly one of the greatest drawbacks to treatment by radiation was the great expense involved. He had had no experience of the treatment of ovarian carcinoma by radiation. He had not yet had time to make any observations on the intensive treatment of menopause symptoms.

Dr. C. D. LOCHRANE (Derby) asked Dr. Knox regarding his experience of the efficiency of radium emanation as compared with radium in treatment. He said that the larger cities in the country were generally fortunate in the possession of more or less large quantities of radium salts, but the same could not, unfortunately, be said of the smaller provincial hospitals. There had been a tendency in some quarters recently to discredit the efficiency of even the most carefully prepared emanation, but if the emanation were equally to be trusted the scope for the applicability of radium treatment in gynaecological and other cases throughout the country would be greatly extended. With regard to the prolonged and

repeated application of x rays to the ovarian regions in the effort to control uterine haemorrhage the danger had not been emphasized of producing more or less serious damage to the blood cells. That this was a real danger had been recently demonstrated, and made one hesitate to recommend prolonged ovarian raying in cases apparently suitable for hysterectomy or myomectomy. He also asked what was Dr. Knox's experience of the effects of x rays on leucoplakia of the vulva. He had had no beneficial results in two recent cases of his own.

In answering the questions of the last speaker Dr. Knox said that equally good results could be obtained from the use of emanations as from radium. He entirely agreed that in massive exposures the effect on the blood must be very carefully watched. Toxaemia might be produced if a very large dose were given. He agreed that the treatment of leucoplakia by radiation was very unsatisfactory.

THE TREATMENT OF SALPINGO-OÖPHORITIS.

BY

JOHN CAMPBELL, M.A., M.D., F.R.C.S. ENG.,

Surgeon to the Samaritan Hospital for Women, Belfast.

INFECTIONS of the Fallopian tubes have been classified as ascending and descending. Those of the ascending group are the most important and include inflammations started by agents, such as the gonococcus, the streptococci, and the staphylococci, which reach the tube by way of the vagina and uterus. The descending infections are due to organisms which are supposed to invade the tube from the bowel, the peritoneum, or the blood. They include the bacillus of tubercle and *Bacillus coli*. When you come face to face with a case of salpingo-oöphoritis, acute or chronic, it is impossible at present to make a clinical distinction between these two groups. Hence treatment must, as a rule, be considered in its broad general relation to inflammation, be the infective agent what it may.

There is such a sharp line of demarcation between acute and chronic inflammation of the tube and ovary that the treatment of the two varieties requires to be dealt with under separate headings.

I. ACUTE SALPINGO-OÖPHORITIS.

Whatever the cause of this condition may be, it is still treated by the majority of gynaecologists on the expectant plan. Rest in bed until the temperature has been normal and the patient has been free from pain for a considerable time, laxatives, counter-irritation, and copious vaginal hot douching with saline solution or some weak antiseptic agent are the principal measures usually relied on. Morphine may be required to relieve pain. When there is purulent urethritis, or inflammation of Bartholin's glands, or other condition which makes it probable that the gonococcus is the exciting cause, washing out the vagina with argyrol (20 per cent.), or protargol (10 per cent.), or other weak silver preparation is a reasonable and probably a beneficial thing to do. In a course of expectant treatment there are two things which must be avoided—namely, repeated vaginal examinations and attempts to apply local treatment to the cervical canal and uterine cavity. Both are useless and both are an infringement of the important principle of rest for the inflamed parts. Any handling of the pelvic organs is likely to cause a spread of the infection.

It will be apparent that this hitherto popular policy is simply one of "wait and see." The best that can be said for it is that it gains time and gives nature a chance. The modern abdominal surgeon has good reason to regard nature as a very uncertain lady, and it may be safely affirmed that such a programme will no longer satisfy the requirements of such a progressive art as present-day gynaecology is. An acute salpingo-oöphoritis is very much akin to an acute appendicitis. Just as leakage from a burst vermiform appendix is the chief source of danger to the patient; so also is leakage from an inflamed Fallopian tube the main thing to be feared. An acutely inflamed appendix is now removed as soon as it is recognized or even suspected to exist. Why should not an acutely inflamed tube be treated in the same way? It is true that in tubal cases the inflammation is only part of an extensive affection which involves the uterus as well as the tube; but the tube is the important structure. The patient's life is in danger from it, and not from the inflamed uterus. It is also true that a woman regards her

vermiform appendix as a useless and uninteresting organ which she is quite willing to get rid of when it gives her trouble, while she will part with her Fallopian tube with reluctance, even when it is a source of inconvenience. This is a matter of sentiment. An acutely inflamed tube is likely to be permanently useless, and is as likely to be a lasting source of trouble and risk as an acutely inflamed appendix. There does not seem to be any substantial reason why an inflamed tube should be treated on expectant lines and an inflamed appendix removed as soon as possible.

The expectant treatment of acute tubal inflammation has survived because we are influenced by a habit of thought which has outlived its time. What is good in the appendix case would appear to be equally good in the tubal case. However sound this view may be in theory, it must be admitted that operations on acutely inflamed tubes have in the past not been very successful. Why is this? I think it is simply a question of time. Until recently operations were only performed on those cases which were rapidly going from bad to worse under expectant treatment. They were done too late, when the condition was already hopeless. I remember when operations on cases of acute appendix inflammation were so dangerous as to be questionable. This was simply because they were done too late. A fuller knowledge led to earlier operation, with most gratifying results.

Tubal cases have not been operated on as soon as they were diagnosed. Time has been lost in carrying out expectant treatment, and the case has only been operated on when the prospects of success were doubtful. If the public and the profession recognized the fact that an inflamed tube should be removed at the earliest possible moment, I see no reason to doubt that operations in acute tubal inflammations would be as successful as they are in acute appendix inflammations.

If we admit the advisability of early operation in acute salpingo-oöphoritis, it is necessary to consider the kind of operation best suited to the condition. An incision in the posterior vaginal fornix and the insertion of gauze drains into the pouch of Douglas has been advocated. It is claimed that in cases so treated the tubes never suppurate. No organ is removed. The gauze drains are depended upon to turn the scale in favour of recovery. The adherents of this method admit that it is much more suitable for gonorrhoeal than for septic cases. How are we to say for certain that an acute case is purely gonorrhoeal in origin? We cannot do it. Moreover, the operation does not remove the tube, which is the chief source of present and future danger to the patient. It is simply a kind of extension of the expectant line of treatment.

The more rational plan is to open the abdomen in front, inspect the affected organs, and remove everything that is considered to be a source of danger to life. As a rule, the inflamed tube or tubes will be the only structures needing excision. The ovarian inflammation, being secondary to the tubal condition, will subside, and the ovaries need not be removed, in part or wholly, unless there is good ground for interfering with them. In women under 40 every effort should be made to leave as much ovarian tissue as possible. It will save time if we defer any mention of drainage in these cases until later on.

It may be fairly objected that the woman will be barren after the removal of both her tubes for acute inflammation. What is the alternative? Without early operation she will probably be barren, and will ultimately have to get her tubes removed after years of suffering, and when dense adhesions have formed and made the operation more difficult. When one tube only is so inflamed as to require removal there is good reason to hope that the operation will give the other tube a chance of remaining capable of functioning. The woman will run less risk of being barren after a unilateral operation than she would have run had there been no operation. Upon the whole the weight of the argument would appear to me to be in favour of removal of the inflamed tube at the earliest possible moment.

It must be always borne in mind that delay in a tubal case is as unwise from the operative standpoint as delay in an appendix case. The earlier the operation is done the more likely is it to be successful. I would here like to be allowed to go beyond the limits of the present discussion so far as to say that in appendicectomy in women the incision should always be made in or near the middle line so that inspection of the ovaries and tubes may be possible. The lateral incision does not give proper access to the pelvic organs. Many cases diagnosed as appendical turn out to be tubal or

ovarian. Therefore I think the median incision should, in most cases of appendicectomy in women, be chosen in preference to the lateral incision.

II. CHRONIC SALPINGO-OÖPHORITIS.

In the present state of professional practice in acute cases the vast majority of patients drift over into the category of chronic salpingo-oöphoritis and go through a prolonged period of ill health, many in the end being compelled to seek relief from operation. Rest, douching, vaginal tampons of iodoform, or other medicament, treatment at health resorts, and many other devices have been employed to relieve the sufferers. A certain degree of success is attained by such remedial measures. In the majority of chronic cases there can be no objection to a trial of these palliative methods. Each practitioner will uphold the efficacy of his favourite line of treatment and will relate the histories of cases which support his views, but a calm consideration of the situation will show that changes for the better are produced by lapse of time rather than by the efforts of the doctor. While the patient is kept in good heart by harmless medical attention, nature gets a chance of repairing the damage as far as she can.

Chronic salpingo-oöphoritis produces two classes of patient: (1) in one the symptoms of disease become absent or trivial, and the woman seeks advice on account of her barren condition; (2) in the other class the patient suffers from more or less pronounced general ill health, and complains much of pain and discomfort of pelvic origin. Recurrent attacks of acute inflammation are not uncommon.

1. In the case of women whose main trouble is sterility expectant treatment finds its chief place. The use of mercury by vaginal insertion or otherwise has been credited with cures. Nowadays the Wassermann reaction will enable us to decide whether antisyphilitic treatment is worth a trial. Dilatation of the cervix and curetting of the uterus is often done, and is occasionally followed by conception. It may be argued that curetting makes the uterus more healthy, and thus gives the tubes a better chance of recovery from the effects of an ascending infection. Is it not more likely that, when conception follows this operation in a case of chronic salpingo-oöphoritis, the success is due to the bursting of a hydrosalpinx, which leaves a patent tube in place of one which has been long sealed up?

Massage of the uterus and tubes has been advocated. This method has never met with much favour among British gynaecologists. We have not sufficiently recognized its merits in properly selected cases of sterility following an attack of salpingo-oöphoritis. It tends to break down adhesions, and it probably sometimes tears away adhesions of the fimbriated end of the tube, thus allowing the fluid of a hydrosalpinx to escape and restoring the function of the tube so that the ovum is enabled to reach the uterus. Notwithstanding its obvious drawbacks and dangers I think pelvic massage should get a fair trial in suitable cases of sterility due to chronic salpingo-oöphoritis. Done by a nurse pelvic massage is not of much value. It is a method of treatment which should receive the attention of lady practitioners of gynaecology. In their hands it would be free from many of the objections which might be raised against it. There is no doubt that in some cases of sterility due to an old salpingo-oöphoritis pregnancy has followed a carefully carried out course of pelvic massage.

In spite of the use of expectant measures, including curetting and pelvic massage, a large proportion of these cases remain barren, and we have to resort to abdominal operation. Excision of more or less of the ampullary portion of the tube will be required, and a new month must be made for the tube by stitching the cut edges with fine catgut. Twedy's method of passing fine stiff catgut along the tube into the uterus and leaving it to act as a sort of temporary bougie or drain is possibly of some advantage. The question as to whether the ovary should be left entire or whether a portion of it should be excised must be left to the judgement of the surgeon. As the operation is being done on account of sterility, needless to say, the ovaries should be damaged as little as possible. It is essential that the ovary should, if necessary, be fixed near the new month made for the tube.

2. We come now to the consideration of those chronic cases which lead lives of pelvic pain and misery, with or without recurrent acute inflammatory attacks. For them palliative or expectant methods are comparatively useless. Operation is the one thing needful, provided that there is no evidence of syphilitic infection, or, if there is such evidence, that

antisepsis treatment has failed. The operation should always be abdominal. In saying this I do not exclude the palliative value of opening an acute abscess which is pointing in the vagina or elsewhere. This is merely a temporary expedient. The extent of the abdominal operation must be determined by two circumstances—the age of the patient and the gravity of the condition.

In regard to the consideration of age it is better, in a woman over 40, completely to remove both the tube and ovary and take no chances of her having pain or discomfort from an ovary or a portion of an ovary left behind. In younger women the most conservative operation possible should be performed, and the patient left with some hope of pregnancy however remote. This means the leaving of as much of the uterine end of the tube as possible, the formation of a new mouth for the tube when practicable, and doing the least possible damage to the ovary. In the younger women it is better to risk the future occurrence of some ovarian pain than to render the patient hopelessly barren. In a few bad chronic cases the diseased condition may be so extensive as to make removal of the uterus, as well as of the tubes and ovaries, necessary, irrespective of the age of the patient.

Drainage.—To drain or not to drain after pelvic operations for salpingo-oöphoritis is still the question. Many of us feel safer in all acute and many chronic cases when we have packed the pelvis with gauze partly encased in thin rubber. We may perhaps be regarded as the disciples of the old gang, but many of the younger American surgeons still use gauze drainage. There is much to be said for the method, so strongly supported by Ranken Lylo, of filling the abdomen with saline solution and completely closing the parietal wound. I confess that I am trying hard to persuade myself to discard drainage. There are certain conditions in which I still think drainage is absolutely necessary. When an abscess has been discharging into the bladder or into the rectum, or when the rectum has been torn in the course of a struggle with adhesions, the gauze drain finds a legitimate place.

I shall conclude with the remark that a preliminary colostomy should be done about a fortnight before the pelvic operation is undertaken in all cases in which an abscess is known to have been discharging into the rectum. The colostomy opening should not be closed until three months have elapsed.

Vaccines.—The use of vaccines is of secondary importance. It is an ancillary measure which has its proper place as part of the post-operative treatment.

DISCUSSION.

The President thanked Dr. Campbell for his valuable paper. He noticed that Dr. Campbell had deliberately stated his case in a provocative manner. He himself could not regard the acutely inflamed tube in quite the same light as the acutely inflamed appendix. The chances of efficient recovery in the tube were better. In regard to tuberculous salpingitis, most of them up to the time of operation were unsuspected. It had been found that nearly 10 per cent. of removed tubes turned out on careful examination to be tuberculous. On the question of drainage his own feeling was that drainage should be reduced to an absolute minimum.

Dr. NIGEL STARK (Glasgow) did not think that any analogy could be drawn between the appendix and the Fallopian tube; the conditions were quite different. An acute tube did not become gangrenous and cause such sudden serious danger as might occur at any moment in an acutely inflamed appendix. Again, a distinction must be drawn between salpingitis and pyosalpinx. Even an acute pyosalpinx might die down and leave healthy tubes, and at any rate he did not think that acute pyosalpinx was very common nowadays. An important point to be considered was that of prophylaxis. Gonorrhoea ought to become less common by better education of the public and by venereal clinics. Tuberculous salpingitis was excessively common in Glasgow; nearly every woman seemed to show some evidence of abdominal tubercle. The condition was caused by the ingestion of tuberculous milk in early life, and it was exceedingly damaging to the female generative organs. Sterility was in a great many cases due to chronic tuberculous infection of the tubes and ovaries, and education of the public in regard to this danger was urgently called for.

Dr. FARQUHAR MURRAY (Newcastle), referring to the use of saline in cases of pelvic inflammation, quoted the excellent results obtained after closure of the abdomen without drainage. In his opinion saline had an important influence in cases of oozing after pelvic operations, the mechanical pressure of the saline serving to check the oozing.

Dr. S. J. CAMERON (Glasgow) thought that Dr. Campbell had made his analogy between the appendix and the tube in order to provoke discussion. His own view was that if one were sure that he had a pyosalpinx to deal with it was best to leave it alone unless general peritonitis threatened. Dr. Cameron said he made it a rule to drain the abdominal cavity in all cases where the peritoneum had been soiled by pus during the removal of acutely inflamed tubes. He had never regretted the introduction of a gauze drain. Despite the recommendation of some American gynaecologists that the ovaries should always be removed in cases of chronic salpingo-oöphoritis, he believed that an endeavour should be made to preserve healthy ovarian tissue. In chronic cases the uterus as well as the tubes should be excised. Pauhystorectomy should be employed, as otherwise a persistent discharge would issue from the diseased cervix.

Professor LOUISE McILROY (London) strongly objected to the statement that the loss of a tube was purely a matter of sentiment. It was a mutilating operation, and mutilating operations were to be avoided whenever possible. The importance of the internal secretion of the ovary and its influence on metabolism must always be borne in mind when the question of complete removal of both ovaries was considered. She thought that it was very difficult to diagnose gonococcal salpingitis with certainty; a bilateral infection was generally gonococcal. A unilateral infection was easy to deal with. She strongly agreed that the median incision in women was the ideal one when dealing with all conditions in the lower abdomen. She was in favour of drainage by the vagina, even in appendix cases; she had completely given up abdominal drainage, and was sure that she had saved many lives by vaginal drainage. In regard to sterility she urged that the husband should always be examined to determine whether or not he was responsible for the sterility. She thought that in the chronic inflammatory conditions radiant heat was much better than douching. Pelvic massage was very useful but difficult to apply without an experienced operator. She asked whether Dr. Campbell had had any experience of inflating the tube with air to break down adhesions.

Professor MUNRO KERR (Glasgow) expressed the view that salpingitis should be divided into: (1) acute primary salpingitis; (2) chronic salpingitis, with (a) an acute phase and (b) a quiescent phase. Acute primary salpingitis, he thought, comparatively rarely called for immediate operation, but, when it was necessary, simple removal of the tube or tubes would not be sufficient unless the uterus was also removed, as it also was infected. He preferred to pack off the pelvis with gauze and drain through the vagina. In regard to the treatment of the acute phase of a chronic salpingitis, he thought it certainly was a debatable point as to the best time to operate. He personally thought it was better to wait until the acute phase had passed; if necessary, simply draining by the vagina. Later on in the quiescent phase, if both tubes were in a hopeless condition, then he considered that they should be removed, together with the uterus and cervix. Free drainage was thus secured. Nothing was to be gained by leaving behind a diseased uterus.

Professor R. J. JOHNSTONE (Belfast) said that he knew Dr. Campbell, and he did not think that he should be taken too seriously. He was somewhat surprised himself at the comparison being made between the appendix and tube. In regard to the removal of pus tubes, he thought there was a form of tube where it was advisable to leave the uterus behind; he referred to those cases where the uterine stump was healthy. On the subject of the vexed question of drainage, his experience had been varied. He had started originally as an advocate of no drainage. This succeeded for a time, and then he had a disaster; after that he practised vaginal drainage for a time, until another disaster caused him to adopt drainage by both abdomen and vagina. He had since given up vaginal drainage entirely. His practice was always to drain by the abdomen in all cases where there was

much oozing. Blood clot could so readily become infected. Ho preferred drainage by tube to gauze; the latter was so painful when removed.

Dr. CAMPBELL, in reply, maintained that, from the surgeon's point of view, a pelvic inflammation was the same whatever its source might be. He always left behind as much ovarian tissue as was possible. He had not tried inflating the tubes with air. He was not at all convinced that his analogy between the tube and the appendix was wrong; both might burst and leak, thus endangering the patient's life. The treatment of the acute chronic case differed from that of the primary acute case, as the adhesions one knew must be present in the chronic case encouraged one to wait.

VAGINAL INVOLVEMENT IN CANCER OF THE CERVIX.

[Abstract.]

Dr. ARCHIBALD LEITCH (London) called attention to the liability of cancer of the cervix uteri to extend down the vaginal wall. *Post-mortem* examination of several hundreds of cases showed that in 97.5 per cent. the vagina was more or less extensively involved; in fact it was the commonest of all the findings at autopsy. Involvement of the parametrium, of the interiliac lymph glands, and the occurrence of hydro-nephrosis were indeed less common. His argument was that these naked-eye appearances found *post mortem* were an indication of the microscopic spread that would be taking place during life. But in addition to such evidence, he had frequently found lymphatic involvement in operation specimens where a vaginal cuff had been removed, and he held that Worthheim, in advocating the removal of a portion of the vagina in order to enclose the supple cervix, had thus unconsciously done a greater service to radical treatment. Such vaginal removal, however, was not sufficiently thorough. Dr. Leitch in pursuing these investigations had on some occasions encountered irregular proliferations of the vaginal mucosa penetrating the underlying tissues, early epitheliomata in fact, which were quite distinct from lymphatic spread, and he suggested that these were due to the same cause, possibly an endogenous irritant, which had produced the original malignant tumour of the cervix. They were later in manifesting themselves, probably because the vaginal epithelium was more resistant to the causal agent.

THE ETIOLOGY AND TREATMENT OF NON-PYOGENIC NEPHRITIS (BRIGHT'S DISEASE).

BY

W. M. CROFTON, M.D.,

LECTURER IN SPECIAL PATHOLOGY, UNIVERSITY COLLEGE, DUBLIN,
AND PATHOLOGIST TO DR. STEEVENS'S HOSPITAL.

THERE is, with the possible exceptions of the cancer problem and the cause of certain neutre infections such as menses, no more obscure region of pathology than that of non-pyogenic nephritis, or Bright's disease. It is with the hope of stimulating further observations, more extensive and more completely controlled, that I describe the following small series of cases.

The first cases that came my way to observe and treat were just before the war and during my war service in Malta (cases already referred to elsewhere), but from the war cases one could not draw very definite conclusions, since when convalescent these patients were shifted home and lost sight of; all of them improved very considerably under therapeutic immunization.

Before describing cases it may be well to consider briefly the present state of opinion on the subject of nephritis. It is recognized, of course, that acute nephritis is associated with acute infections undoubtedly caused by microbes, and it seems to be accepted that the cause of the nephritis is the same as that of the original lesions—for example, tonsillitis. It is recognized, too, that the chronic disease may follow the acute, and one presumes that it is recognized that the same microbial cause may persist, and that in this class of case the chronic nephritis is due to microbes. In the largest class of cases, however, no microbial cause appears to be recognized, and treatment is purely dietetic and directed to the treatment of symptoms.

H. Maclellan in his recent excellent monograph on the diagnosis and treatment of renal disease assumes the position, if I do not misinterpret him, that protein and casts may be present in the urine but renal disease is not present so long as (a) there is no retention of urea, uric acid, creatinin, and the purin bases, (b) there is no retention of chlorides with consequent oedema, or (c) both. This doctrine appears to me very dangerous from every point of view, for if we adopt it it will tend to prevent our using specific methods of diagnosis and treatment in a large group of cases until the disease is advanced. He himself quotes the fact that experimentally three-quarters of the total kidney tissue may be removed before any accumulation of urea occurs in the blood. Surely this must hold good for destruction brought about by disease, and it is not until approximately a similar amount of essential kidney tissue is interfered with that symptoms of non-protein nitrogen retention (azotæmic type) or of dropsy (hydramic type) occur.

It appears to be logical, then, to take up the attitude that no kidney can be considered undamaged which is letting through blood proteins, especially if casts are present as well, for such kidneys, if the lesion does not progress, may remain physiologically functional during a normal lifetime. Of course, the original lesion may retrogress owing to the removal of the cause and the tubules, the destruction of the canals further tubules, so that sufficient to prevent the appearance of symptoms. On the other hand, the primary illness with acute symptoms may entirely clear up and if the cause is only partly overcome and persists in a less virulent form a slow sclerosis may develop gradually, cutting off the blood supply of the tubules and lead to the strangulation of the whole tubular system.

This sclerosis, as is generally recognized, may follow on an acute attack or begin in an insidious manner and slowly progress. What, then, is the cause of albuminuria without symptoms and albuminuria with symptoms? One may rule out such minor causes as acute or chronic poisoning by iugenic or organic poisons such as lead or turpentine, and one must admit in the treacherous nephritis occurring in France the urine on culture was constantly sterile, but in the cases coming from Gallipoli that I saw, acute or subacute, and in the ordinary cases in civil practice there is no difficulty in isolating micro-organisms from the urine and identifying them, for reasons to be stated below, as the cause of the disease.

The functions of the kidneys are usually stated to be:

1. Excretion of waste.
2. Removal from the body of certain waste products of nitrogenous metabolism.
3. Removal of acid products from the body.
4. Maintenance of the optimum concentration of salts in the fluids and tissues.
5. Excretion of toxic materials artificially introduced.

This list leaves out one of the most important functions of the kidney—namely, the excretion of micro-organisms, or, in strictly localized infections, such as diphtheria, the excretion of their toxins.

The resistance of the kidney to virulent micro-organisms is very remarkable; in only a minority of cases of acute septicæmia from whose blood the kidneys abstract and excrete the causative organism do the kidneys become acutely inflamed and damaged. It is not yet generally recognized that many infections thought to be strictly localized are in reality focal manifestations of a subacute or chronic septicæmia. In my experience in cases of boils, carbuncles, and such like infections the staphylococci can always be recovered from the urine. So, too, in the few cases of scarlet fever I have had to treat streptococci were recovered from it. In a proportion of cases of "rheumatic conditions" staphylococci or streptococci, or both, or *B. coli*, are found in the urine; sometimes other microbes, such as diphtheroids—in all these without, as a rule, any signs or symptoms of nephritis. It is not surprising, then, that in some patients whose kidneys are excreting microbes the kidneys should fall a victim to the microbe and become diseased. The lowering of the resistance of the kidney cells may be brought about by any of the general causes of lowering of general or focal resistance—grief, chilling of the surface, alcohol, or the excretion of abnormal waste products from a distant focus of microbial action—for example, of the intestinal tract, of the bones, and so on.

In all the cases treated by me I have isolated a microbe from the urine; in the majority of cases staphylococci, in a few streptococci as well. I shall be asked at once how I know

these microbes are the cause of the disease. Do they fulfil Koch's postulates? Did they produce the disease in animals? Were they isolated from the animals? Of course not. In how many cases of human disease certainly associated with a given cause can Koch's postulates be fulfilled? In 10 per cent.? If this is so it must be the extreme limit.

If Koch's postulates are not fulfilled what criteria of infectivity are we to accept? The finding of specific antibodies—adapters (a generic name for amboceptor, immune body, substance sensibilisatrice, coferment), agglutinins, and so forth? Perhaps so, but always in the animal body will these antibodies be found for such common microbes as staphylococci, streptococci, diptheroids, and the tubercle bacillus. Fluctuations of the opsonic index may help, but in my experience the following criteria are by far the most reliable—namely, the production of (1) focal reactions, (2) general reactions, (3) cure or improvement, with an antigen made from a microbe or microbes isolated from the patient himself, or alternatively the production of local, general, and focal reactions with an antigen used for diagnostic purposes, such as tuberculin.

Let me take this case first as it is most familiar to most people. It may be said that the tubercle bacillus fulfils Koch's postulates, but it is at least arguable whether the human lung disease is reproducible in animals, for lung tuberculosis is practically never an unmixed infection, while animal tuberculosis nearly always is. Local reactions are of little or no use either for the diagnosis of tuberculosis or any other disease, since the presence of antibodies in the circulation enables an intradermal reaction to occur. Any antigen given under the skin may produce a redness or swelling.

General reactions are more important. My experience is that in the case of tuberculosis, if the tuberculin is given in the prescribed doses, a general reaction is at least 90 per cent. diagnostic, for when a lesion is present it is accompanied by a focal reaction. Indeed the site of the lesion may be made manifest by this focal reaction such as the occurrence of crepitations in an area of a lung where they were previously absent, the increase or decrease of the physical signs or symptoms in a kidney or joint or bone, the increase of discharge from a mucous membrane or sinus, the decrease or increase of albumin in the urine. The late Professor White in a case of discharging wounds or sinuses used to work out the curves of focal reaction by periodical counting of the microbes in the discharge. In nephritis, as I shall show below, the curves of reaction can be precisely worked out by the daily estimation of the protein in the urine. When the lesion is closed to the surface the reaction is very definitely shown by a sudden increase or decrease of symptoms and physical signs—in a knee-joint, for instance, or in the central nervous system in epidemic meningitis or encephalitis. The sensitiveness to small doses of the infecting antigen is very remarkable. For instance, in tuberculosis I have quite often produced a slight but definite general reaction after a dose of 0.00000001 mg. H.T.S., while in a patient without active lesion 0.1 mg. has no effect. In mucous colitis focal reactions after 1 million (about 0.0003 mg.) *B. coli* antigen are quite common. One might multiply instances indefinitely; on the other hand one could give one hundred times the dose of a non-specific microbial antigen subcutaneously without reaction. Finally, if having given a course of microbial antigen to a patient the lesion retrogresses or completely heals up, it is in my experience 99 per cent. at least probable that the antigen or antigens used are specific.

I have argued many times before the question of the use of non-specific antigens. I shall only ask again, If they are so successful as some would have us believe, why were they such a tragic failure in wound infections in the late war?

Now, if the criteria I have laid down are correct, the identity of the infecting micro-organisms is completely proved, for in the majority of cases to be described there were general and focal reactions and marked retrogression or cure in almost every case. I have only lost one patient so far, and he was so far advanced that no hope of recovery could be entertained; I have not therefore described his case.

Albuminuria without Obvious Oedema.

CASE I.

A patient of Dr. Cooke, a man aged 28, seen first in 1914. Had been rejected three times for life insurance on account of albuminuria. The amount was 1 gram per litre. Staphylococci isolated. The doses given were 10, 25, 50, 75, 100, 150, 200 million. The albumin disappeared after the 100 million dose. The patient then disappeared for three months, but was still free from albumin when he turned up again, and has remained free since.

CASE II.

D. B., aged 17. Seen in 1919. Laboratory assistant. Had been cured of tuberculous glands in neck with tuberculin (H.T.S.). Was pale and easily tired. He found distinct cloud of albumin in his urine on several occasions. Cultures of special specimen gave culture of *Staphylococcus albus*. He was given doses of 10, 25, 50, 75, 100, 150, 200, 300, 400 million. The albumin rapidly disappeared, and has remained absent since (September, 1922).

CASE III.

Medical student, aged 26. Seen first February 25th, 1920. For three years or more noticed frequency of micturition during the day, especially during cold weather. Examination of mixed twenty-four hours' collection gave 0.75 gram per 1,000 albumin. *S. albus* isolated. Doses 10, 25, 50, 75, 100, 150, 200, 400, 600, 800, 1,000, 1,500, 2,000, 3,000, 4,000 million given at suitable intervals according to reactions. After the 200 million dose the albumin which had reduced to a trace increased to 0.5 gram per litre and then gradually disappeared, three weeks' interval being left. He remains now (1922) completely free from albumin.

CASE IV.

Boy, aged 6. Seen first on November 10th, 1921. Sent to me by Dr. Straugman for chronic bronchitis, asthma, and constipation. The boy looked pasty, and on examination of a sample of a twenty-four hours' collection

Case IV. Focal reactions.

it was found to contain about 0.5 gram per litre of albumin. From his sputum were isolated *S. albus*, *M. catarrhalis*, and streptococci. *S. albus* was isolated from his urine and *B. coli* from his faeces. A mixed antigen was made. I omitted the *S. albus* from his urine as I was anxious to see whether the *S. albus* from his sputum would produce focal reactions in his kidneys and thus confirm my opinion as to its probable mode of entrance into his circulation. These focal reactions occurred early in his treatment, and very prettily demonstrated the occurrence of focal reactions in the kidneys.

The series of doses was—

<i>S. albus</i> .	<i>M. catarrhalis</i> .	Streptococci.	<i>B. coli</i> .
10	+	12	+
25	+	25	+
50	+	5	+
50	+	5	+
75	+	75	+
100	+	10	+
and so on to			
2,000	+	200	+
	+	200	+

Some of the doses had to be repeated owing to focal reactions in his lungs. After the second dose of 175 + 175 + 175 albumin completely disappeared. His treatment was concluded on February 2nd, 1922, and he has remained well since.

These cases will suffice to illustrate the functional albuminuria type of case. I have not so far met a case in which I did not isolate a microbe from the urine and cure it by immunization. But my experience is still small.

Cases with Obvious Oedema.

CASE I.

Constable X, aged 30. Admitted to Dr. Steevens's Hospital under Dr. Kirkpatrick, October, 1916, with general oedema and a heavy cloud of albumin. When I saw him he had lost the oedema under ordinary treatment, but still had 1 to 2 grams per litre of albumin. I isolated *S. albus* from his urine. Doses of 10, 25, 50, 75, 100, and 200 million were given at suitable intervals. At the end of three weeks albumin had completely disappeared from his urine, and he was sent home apparently cured at the end of four weeks.

CASE II.

J. B., aged 14. Came under my care in February, 1918, with generalized oedema, severe headache, and amblyopia. She was passing 50 oz. of urine containing 1 gram per litre of albumin, and giving a profuse growth of *S. albus*. Temperature normal. After the first dose, 25 million of antigen, there was a general and focal reaction, her temperature going to 99.4° for two nights, her oedema and headache increasing and her urine to 3½ pints, containing still 1 gram per litre. The doses were increased at suitable intervals to 4,000 million, when the urine contained a bare trace of albumin and the patient had no symptoms. On re-examination five months after a catheter specimen still contained a trace of albumin and isolated, so she was given a second course a dose of 100 million and increased to 200 million. She had then been free of albumin and microbes for some time, and remains so still (September, 1922).

CASE III.

J. C., aged 18, admitted to Dr. Steevens's Hospital in an unconscious state, under Dr. Kirkpatrick, November 29th, 1919, having had a fit on a railway station platform on his way home.

He gave a history of three weeks' illness. He had general oedema, evening temperature 101° F., pulse 124. He was bled, given an enema and hot pack, with only water to drink. He recovered consciousness under this treatment. I saw him a fortnight after. He was then generally oedematous, passing 20 oz. of urine, which contained a large quantity of albumin and a few pus cells. *S. albus* and streptococci were isolated. He was given 25 million staphylococci antigen + 2½ streptococci antigen on December 18th, 1919, and the doses were increased to 1,000 + 100. The series was 25 + 2½, 50 + 5, 75 + 7½, 100 + 10, 150 + 15, 200 + 20, 300 + 30, 400 + 40, 800 + 75, 1,000 + 100. He had distinct focal and general reactions after the first few doses. After the first his temperature went to 101.8° F., and his urine increased from 20 to 40 oz. in twenty-four hours. He was discharged apparently cured on February 11th, 1920.

CASE IV.

J. K., aged 39, labourer, was admitted into Dr. Stevens's Hospital on December 23rd, 1919, with severe headache and general oedema. He was passing 15 oz. of urine loaded with albumin. He gave a history of several similar attacks. When I saw him at the end of January, 1920, he was still oedematous and had severe headaches. His urine contained 4 grams per litre of albumin, and he was passing about 70 oz. in the twenty-four hours. *S. albus* was isolated from his urine and 5 million antigen was given on February 2nd, 1920. The series of doses was 5, 10, 15, 20, 30, 40, 50, 60, 75, 100, 150, 200, 300, 400, 600, 800, 1,000, 1,250, 1,500, 1,750, 2,000. He steadily improved, losing his headache and oedema, and was discharged May 9th, 1920, his urine containing 0.75 to 1 gram per litre. He returned to work June 20th, 1920, and has remained in full work ever since. His urine now (September, 1922) contains 0.5 gram per litre, so that the improvement in his kidneys has continued.

CASE V.

P. C., aged 14, admitted Dr. Stevens's Hospital under Dr. Kirkpatrick with general oedema. Temperature 101° F., pulse 104. Urine contained blood. *S. albus* and streptococci were isolated from his urine, and on March 2nd he was given 10 million staphylococcus antigen + 1½ million streptococcus antigen; the series of doses was: 10 + 1½, 25 + 2½, 50 + 5, 75 + 7½, 100 + 10, 150 + 15, 200 + 20, 400 + 40, 600 + 50, 800 + 75, 1,000 + 100, 1,500 + 150, 2,000 + 200. The focal reactions in this case were very pronounced after the third dose; for instance, the albumin, which was 1.5 grams before the dose, increased to 4 grams on the next day, and then fell to 1 gram on the fifth day after. The boy left hospital on June 7th, 1920, with a bare trace of albumin. He has remained well since and is now (September, 1922) quite free from albumin.

CASE VI.

Girl aged 17, under the care of Dr. Pepper, gave a history of chronic nephritis with acute exacerbations for many years. When she came under treatment she was suffering from violent headache, general oedema, and her urine contained 2 grams per litre albumin. Staphylococci and streptococci were isolated from her urine. She was given 5 million staphylococcus + 1 million streptococcus antigen, which was steadily increased until a dose of 4,000 + 500 million was attained. The patient had then greatly improved. Her headaches had greatly diminished and her oedema had disappeared. The albumin had reduced to 0.75 gram per litre. She is now (September, 1922) in good health; no oedema of her legs, her only symptoms being occasional slight headaches. Her urine still contains 0.7 gram per litre albumin.

CASE VII.

V. F., a boy aged 5, admitted to Dr. Stevens's Hospital under Dr. Winter, October 19th, 1921, with general oedema and headache, passing 10 oz. urine containing over 12 grams per litre of albumin. The albumin fluctuated in an extraordinary way, being sometimes as low as 0.5 gram and as high as the V mark on the Esbach tube. When I saw him in December, 1921, his oedema and general condition had greatly improved, but he had still an enormous quantity of albumin. Staphylococci and streptococci were isolated. He was given 5 + 1, and had a very distinct increase of oedema after this and several other doses. As the albumin did not show any improvement after the 50 + 10 dose I reinvestigated the bacteriology of his urine, and found as well as the other microbes a coliform bacillus. The addition of an antigen of this did not, however, make any difference, and he left hospital May 31st, 1922, in very good general condition, but still passing as much albumin as ever. Evidently his kidneys were irretrievably damaged. The initial dose was 5 million staphylococci + 1 million streptococcus antigen, and the series was: 5 + 1, 7½ + 1½, 10 + 2, 15 + 3, 20 + 4, 30 + 6, 40 + 8, 50 + 10, 60 + 10 + 2½ (coliform antigen), 75 + 15 + 5, 100 + 12½ + 7½, 150 + 20 + 10, 200 + 25 + 12½, 300 + 30 + 15, 400 + 40 + 20, 500 + 50 + 30. This boy now (September, 1922) is playing about like a normal child with no sign of illness, but has still 3 grams per litre of albumin. His after-history will be interesting.

I could add other cases, but I hope these will sufficiently illustrate the possibilities of the treatment. Even if complete cure is not possible one can often, as in Cases IV and VI, restore them to good health and full working capacity. If the cases are taken in time, complete cure ought to be possible in the large majority of them. I am as ever deeply indebted to my colleagues at Dr. Stevens's Hospital for their cases at my disposal.

RESTORATION OF THE SUNKEN NOSE.

BY

HAROLD BURROWS, C.B.E., F.R.C.S.,

ASSISTANT SURGEON, ROYAL PORTSMOUTH HOSPITAL.

THE practice of making good a defect of the contour of the nose by inserting a graft of cartilage beneath the skin is one the soundness of which is sufficiently well established. Nevertheless, I suppose that most surgeons have sometimes had cause to lament that the practical result has fallen short of the ideal. This being so, any little idea that may help toward the achievement of better results will be acceptable. I would like, therefore, to describe the operation which I have employed, in order to introduce a mechanical detail which has been of considerable assistance.

FIG. 1.—Cast of nose before operation. (In addition to the sunken bridge there is considerable deformity of the anterior nares, from old ulceration.)

FIG. 2.—Cast of same nose after operation.

Preliminary Measures.—The first step is to obtain a plaster cast of the patient's nose and neighbouring features. Having acquired this, the nasal defect which is shown in the cast is filled with plasticine, which is moulded with care so as to produce on the plaster model the shape of nose which it is hoped to reproduce on the patient. This plasticine model of the nasal defect is then removed from the plaster cast and well powdered with boric acid. This dries the plasticine, which, when dry, is less likely to become altered in shape under subsequent handling.

FIG. 3.—Plasticine models. The two small pieces represent grafts used to stiffen the alae nasi, which were sunk and lacking in cartilaginous support.

With a small metal caliper the length of the plasticine model is measured.

Operation.—With the patient under general anaesthesia the right fourth rib cartilage is removed. The separated fragment is replaced in its bed and the skin wound temporarily closed with towel clips. This having been done, a transverse incision is made across the nose at the level where the bridge of a pair of spectacles would naturally rest. Through this incision the skin of the nose is separated from the underlying structures over the whole area of the nasal defect. The towel clips are now taken from the chest

FIG. 4.—Metal caliper for measuring the grafts.

length as shown exactly by the caliper. Then, with the plasticine model held in front of him by a nurse who can manipulate it as required, the surgeon carves the piece of cartilage in the likeness of the clay model, and having completed this fashioning the graft is slipped into its bed in the nose, the skin incision being closed by two or three horseshair sutures. The chest wound is then sewn up and a dressing applied. But no dressing other than a dusting with boric powder is used for the nose.

After-Course.—The horseshair stitches are removed on the fifth day. The cartilage graft having been properly modelled lies comfortably in its bed without any tendency to slip out of place.

Comments on the Operation.

1. By raising the bridge of the nose an epicanthus can be eliminated.

2. Scarring of the skin of the nose from previous trauma or disease interferes considerably with the cosmetic result of the operation just described.

3. In many cases the defect is too deep to be filled by a single cartilage graft—as, for example, in those instances in which a patient can see one eyeball with the other eye. Here the operation is duplicated. The right fourth cartilage is used for the first operation, and at the second operation, which is done only after an interval of one year or longer, the left fourth rib cartilage is used to complete the filling of the defect.

4. Cartilage, especially when wet with normal saline, is a slippery substance to hold, and unless he is well on guard against such an accident the surgeon may find the graft slip out of his fingers and come to rest upon some unintended and infected landing place.

5. In one instance the cartilage graft shifted after the operation had been completed.

This was in a case of a very large defect, and during the first operation it occurred to me that I might be able to remedy to some extent the forward prospect of the nostrils by making the cartilage graft somewhat longer than the plasticine model, so that when inserted it would thrust downward the lower end of the nose. There was such a deep ledge for the graft to rest against at the upper end of the defect that I thought dislocation was impossible. However, the graft did gradually become displaced, the upper end slipping forward and upward.

Had this displacement taken place laterally, or had the case been one where a single graft only was needed, the accident would have been most unfortunate. As it is, however, probably no irregularity will be noticeable when the second stage has been completed. In any case, I do not now think it was sound practice to attempt an elongation of the nose by inserting a graft large enough to cause considerable pressure and counter-pressure.

INJURY TO THE BOWEL WITH RECURRENT HAEMORRHAGE.

BY
MAURICE HORAN, F.R.C.S. EDIN.,
SURGICAL SPECIALIST, WAR PENSIONS HOSPITAL, SANDERLAND.

THE following case is recorded as one of interest on account of the long history and intermittent character of the symptoms, of which haemorrhage was a prominent feature. It has been suggested that the recurrent haemorrhage was due to the formation of an aneurysm in a vessel at the site of injury in the bowel, which appears to be the most probable explanation of the case.

Pensioner J. B., aged 35, was admitted to hospital on January 13th, 1922. In 1917, while serving in the trenches during shelling, he was struck in the abdomen by a sandbag blown in from the parapet. He was seized with abdominal pain, shortly followed by the passage of a considerable quantity of blood in considerable couple of weeks, haemorrhage occurring, he was transferred to England. While in hospital there he had two more severe haemorrhages from the bowel accompanied with pain, and the question of operation was considered. This was eventually negatived, and he was discharged some time later. Since then haemorrhage, similar in character but slight in amount, generally followed the taking of solid or more particularly of indigestible food. The haemorrhage was always accompanied with pain. He voluntarily restricted himself to a diet mainly of slops, and from being a professional footballer had refrained from exercise.

On examination tenderness was present in the left side of the abdomen, to which area the pain was referred. Nothing else was detected. Rectal examination was negative. In the course of preparation for a laparotomy which was decided on the administration of an enema was followed by a good deal of pain and the passage of a quantity of dark-coloured blood.

The abdomen was opened to the left of the middle line and the gut was systematically examined. Two small areas of scarring, without deformity, were present in the lower part of the ileum. In the lower part of the jejunum a circular area of bluish discoloration of the size of a farthing and resembling a haematoma was present on the antimesenteric surface of the gut; extending from this, to the root of the mesentery, was a cord-like deposit of lymph. On palpating the gut a definite area of thickening corresponding to the discoloration was felt. The remainder of the bowel appeared normal, as did the other viscera. The portion of gut containing the lesion was resected and the continuity of the bowel restored by anastomosis. He made an uneventful recovery and was discharged from hospital on February 23rd, 1922. He has since returned to ordinary diet, and there has been no recurrence

of the pain or haemorrhage; he expresses himself as being quite well.

The specimen removed, on section, presented the appearance of a haematoma, dark clotted blood occupying the space between the mucous membrane and outer wall of the bowel. The muscular coats were torn, blood being extravasated throughout, and in direct contact with the mucous membrane, which appeared intact.

My thanks are due to Surgeon Captain Bishop, R.N. C.M.G., administrator of this hospital, for permission to record the case.

Memoranda:

MEDICAL. SURGICAL. OBSTETRICAL.

A CROSS-WIRE AXIS FINDER IN ASTIGMATISM.

THE following description of a very simple piece of apparatus may be of interest to those who are engaged in refraction work, for it saves a great deal of time, tends to efficiency, and is so small that it can be carried in the ophthalmoscope case. It consists of a ring, the exact size of the trial-lens mount, across the middle of which stretch two fine wires at right angles to one another.

In retinoscopy, if a band of light is seen, or if one appears in the course of correction, this cross is placed in the front cell of the trial frame in such a position that one of the wires is exactly parallel to the edge of the band. This wire is in the axis of astigmatism, and where its extremity appears to meet the scale will give the reading required. The wire is very easily seen as a fine black line against the illumination of the fundus.

There are now four ways of checking the finding:

1. Move your own head slightly sideways, so that the wire is up and down the middle of the band. If now the black line appears parallel to the edges, and does not approach them at an angle either at the top or at the bottom, the axis is indicated correctly.

2. Move your light along the second wire, and if the band keeps at right angles to this and follows the same direction, not sneaking off above or below, the axis is correct.

3. Overcorrect considerably, and the band will appear turned into the other meridian, and should then have the second wire exactly up and down its length.

4. Put a cylinder into the frame, with its axis over the meridian of the wire. If the wire is right there will not appear to be any rotation of the band now; if the wire is wrong the band will appear to be rotated through quite a perceptible amount, this rotation depending partly on the amount of error and partly on the strength of the cylinder used. This is a delicate check, as the error is magnified, so that, say, five degrees of error will send the band round through ten or fifteen.

My instrument was made by removing the brass rim from a trial-box lens and forming the cross of the fine wire used by florists, but it is difficult to get the wires exactly at right angles and to have the crossing point exactly in the centre. I have used it for the last twelve months, doing difficult refractions at an average rate of sixty a week, and find that in nine cases out of ten it gives the cycloplegic correction straight away. The failure in the tenth case is due to fatigue in the observer and is not instrumental in origin. Messrs. Dixey, 3, New Bond Street, will make the apparatus for anyone who requires it.

Southampton.

JOSHUA KEYMS, M.D.

THE THIRD STAGE OF LABOUR.

Is anyone prepared to give an authoritative statement why in some cases pressure on the fundus uteri readily delivers the detached placenta and in other cases pressure sufficient to hurt the patient has no effect? The other day I attended a multipara and the second stage made me think I would have an easy time with the after-birth. In twenty minutes, with the easy confidence engendered by the second stage, I pressed on the fundus and there was no satisfactory opening of the vulva that indicates a speedy end. Having ample time I decided to be patient, but after several unsuccessful attempts, including traction on the cord (*Clinical Obstetrics*, Jardine), I found ninety minutes had passed since the child was born, so I proceeded to remove the placenta manually. As I expected, I found it lying in the upper strait of the vagina. It seemed to me that synchronously with my looking

my finger round the edge of the placenta gentle pressure on the fundus delivered placenta and membranes. There was no tacking back of the latter.

Meditating on this case—and I know my experience is not unique—I thought that the easy cases might be those in which the after-birth comes through the os sideways, and the difficult cases those in which the after-birth comes through the cervix in such a fashion that it lies covering the fornices and the os. The placenta and cord bear the relation, in these circumstances, to the soft parts that the leather sucker of the little boy bears to the stone on which he has tramped it. Atmospheric pressure is in force. In the above case I did not pull on the placenta, I simply hooked my finger round the edge.

To have to introduce one's hand into the vagina for the placenta is distressing, but this distress would be mitigated if those in authority had stated that such procedure was justifiable because necessary and unavoidable.

Kilnhurst.

CHARLES J. HILL AITKEN, M.D.

VENESECTOMY IN ECLAMPSIA.

I recently attended a woman, aged about 30, in her second pregnancy. Apart from having defective teeth she had a sound constitution. Her first pregnancy was normal. Albumin was found in the urine about the sixth month of the second pregnancy. In spite of treatment she began to suffer from severe headaches, swelling of the legs, and puffiness of the eyelids. On my advice at about the commencement of the ninth month she consented to rest entirely in bed; four days later, during the night, she lost her sight, and several hours later eclampsia set in and labour commenced.

The bowels were emptied by enemata. Labour progressed slowly but normally. On the following afternoon the convulsions became more frequent and violent. At about 3 p.m. I performed venesection (median basilic), removing about 30 ounces; she had two convulsions during the operation, and chloroform was administered. Afterwards no more convulsions occurred, but the patient remained unconscious; labour progressed normally, and at 11 p.m. I found the membranous sac intact protruding from the vagina; the infant was dead. After waiting half an hour I extracted the placenta with difficulty, owing to the fact that the uterus was firmly contracted. There was very little haemorrhage.

She was unconscious for some time afterwards. The blindness lasted all the following day and night; when sight returned it was for some time disordered, but ultimately the recovery was perfect.

I have since assisted at another case of eclampsia where the toxicity was not so intense; the labour progressed quite normally in spite of the eclampsia, and the child was living.

In my experience of eclampsia there is no necessity to interfere with the progress of labour, and certainly not before the third stage; but venesection should be performed, and I think at an early stage; the amount of venous blood to be removed will depend on the degree of toxicity. A record of the average blood pressure in pregnancy and of eclampsia would be interesting, and may be of use in regulating the amount of venous blood to be removed.

I have previously recorded an example of the beneficial effects of venesection when eclampsia persisted after the birth of the child; and when by cutting the umbilical cord after it had been ligatured and allowing it to bleed freely, artificial respiration being used also, the infant's life was preserved.

Bradford.

EDGAR W. SHARP, M.B.

Reports of Societies.

THE WAR SECTION OF THE ROYAL SOCIETY OF MEDICINE.

The first sessional meeting of the War Section of the Royal Society of Medicine was held on October 9th at the Royal Army Medical College, Millbank. The purpose of the meeting, which was attended by more than a hundred members and visitors, was to hear the presidential address of Lieutenant-General Sir John Goodwin, Director-General of the Army Medical Service, but it was announced by Major-General Sir A. P. BLENKINSOP, who took the chair, that Sir John Goodwin was prevented from fulfilling the engagement by reason of his official work in connexion with the Near East crisis.

Sir A. P. BLENKINSOP welcomed the members to Millbank, and went on to review briefly the work of the Section and its future possibilities. There had been a slight increase in membership during the war, but the present membership—a little above 200—was a very small proportion of the members of the medical services. In one of the Commands every officer had lately been asked to join the Section, and had received literature on the subject of its work, but the response had been very discouraging. It would be a thousand pities if the Section were to close down. The various military medical services had much to learn from each other, and there was a good deal to be gained by closer co-operation and a freer interchange of ideas, especially on questions of administration, organization, and medical tactics and strategy. The War Section was the only means, so far as he knew, whereby such co-operation could be brought about. Its designation was perhaps inadequate, and the Council would be glad to receive suggestions for some better name. It was advisable also to establish local branches, if possible, at the larger military and naval stations at home and abroad; and if this scheme were approved by the members of the Section it would be submitted to the Council of the Royal Society of Medicine for its consideration. *The Medical History of the War*, now in course of publication, would be a textbook in the medical services for a long time to come, and the members of the Section would join with him in congratulating the editors; but there was no space in that history for a record of individual experiences or the threshing out of controversial matters, and it was here that the work of the Section might well furnish a useful supplement to the official history.

Exhibits at the Royal Army Medical College.

At the close of the address the members of the Section, by invitation of the authorities of the College, visited the laboratories and museums, where special exhibits had been prepared for their benefit. In the hygiene laboratories there was an exhibit of rations, illustrating the present-day peace ration, the energy value of which was given as 2,497 calories, and another which showed the evolution of the emergency ("iron") ration. This at first consisted of chocolate, with an energy value of 553 calories; in 1913 it was elaborated so that it had an energy value of 2,663 calories, and the present-day "iron" ration, dating from 1918, had 2,800 calories. Some special ration constituents were exhibited, including marmite, germinated pulses (possessing marked antiscorbutic properties), lemon juice (which has now displaced lime juice as an antiscorbutic item in army supplies), and acid drops (which are included in the "iron" ration of the Royal Air Force). The army biscuit of the present day was the subject of another exhibit, wherein it was shown to possess for its weight of one ounce an energy value of 104.25 calories.

Some recent developments in water purification were also shown. Bleaching powder used for water purification and other purposes used to arrive in the tropical countries with the chlorine so greatly diminished, owing to the heat and moisture of the atmosphere, as to make it useless for sterilization purposes. Ordinary bleaching powder, after six months' storage in Egypt, was found to contain less than 1 per cent. of available chlorine. Research has been carried out in the College, and it has been proved that by mixing 20 parts of quicklime and 80 parts of bleaching powder ("chloride of lime") a product results which will withstand tropical climates without deterioration. A specimen of this stabilized bleaching powder had contained 25.2 per cent. of available chlorine when sent out to West Africa, where it was stored under ordinary conditions for a year, and at the end of that time it was found to contain 24.4 per cent.—a loss which is negligible for practical purposes. Tins of the stabilized powder which had been kept in Mesopotamia (Iraq) for twelve months were exhibited, and it appeared that the results here were similar to those in the West African samples.

Among other exhibits were certain recording instruments for motion study and for the measurement of energy expenditure by indirect calorimetry; and in the pathological museum there was a specially arranged exhibit of microscopical specimens illustrating malaria, typhoid, and paratyphoid fevers, plague, its cause and method of infection, trypanosomiasis, and the life cycle of bilharzia. Another series of specimens illustrated the effects on the respiratory passages of phosgene and mustard-gas poisoning.

Reviews:

MEDICINE IN THE WAR.

[FIRST NOTICE.]

Good progress has recently been made with the publication of the *Medical History of the War*, which is to form part of the *History of the Great War Based on Official Documents*. Nine volumes are promised. The whole series is being prepared under the general editorship of Major-General Sir W. G. Macpherson, K.C.M.G., M.B. The first volume of the series, containing the general history of the Medical Services, was published at the close of last year and was reviewed in our columns of December 17th, 1921 (p. 1047). The first of two volumes dealing with Diseases of the War,¹ with which we now propose to deal, was issued a short time ago, and the first of two volumes on the Surgery of the War reached us recently.

Considering the difficulties which must attend the preparation of the medical history of any campaign Sir William Macpherson and his collaborators are to be congratulated on the appearance of the first volume on the Diseases of the War within four years of the close of hostilities. Other volumes in preparation will deal with the Hygiene of the War, with Pathology and Medical Research, and with Medical Statistics and Epidemiology. Readers of the volume now under notice will do well to bear this in mind, so that they may not look for comment here on the influence of medical considerations on the general strategy of the war. Nevertheless, the form in which the articles are presented is not a bare description of various diseases after the manner of a textbook or journal. It would be impossible for any writer who was an active participant in the campaign to ignore the effects of disease on the troops as effective fighting units. Had such a plan been followed the articles would have merely constituted a sort of bird's-eye view of the state of scientific knowledge at the end of the war and would have proved of quite ephemeral interest. Such a view would have been of little or no value to future generations, and would give small help to those responsible for the conduct of future campaigns. But some such picture of the state of our knowledge was bound to be presented, and the authors of the articles have succeeded in accomplishing this part of their task without undue prolixity or elaboration. Since it is unlikely that in future campaigns even the known causes of disease can be avoided entirely or prevention secured, the measures adopted in the great war for the treatment of disease and for minimizing the resulting invalidism were well worthy of record.

There are, of course, chapters in the history of our medical services which will never be officially chronicled. The failures and difficulties will not be discovered impartially set forth in these volumes. Only the splendid indiscretion of some private memoir is likely ever to lift the curtain from some of the most important episodes in the medical history of the war. After all, posterity will not be particularly interested to know who was responsible for the inadequate ration in Mesopotamia that produced the beri-beri there. It will be enough to know what the ration was that abolished beri-beri. Who selected the malaria-infested terrain of Macedonia for a "side-show" doesn't matter much from the scientific point of view so long as the lessons of the error are borne in mind. The general impression left after reading this volume is that it is the minor and avoidable ailments that cause the greatest wastage in an army. Science has robbed many of the principal scourges of their dangers in spite of popular belief to the contrary. The most notable example is that of enteric fever, where inoculation has been proved capable of rendering whole armies immune, even when infection was present everywhere. In the South African war the admission rate for enteric fever was 235 per 1,000 and the death rate 36 per 1,000 of the average strength in the British army; in France in 1918 the comparable figures were an incidence rate of 0.12 per 1,000 and a death rate of 0.007 per 1,000. In Egypt, where the disease reached its greatest incidence for any theatre, the figures in 1916 were 17.35 and 0.32 respectively. Certain diseases left our troops almost untouched, notably typhus, of which we had only 993 cases in

all theatres, and famine dropsy, the only British cases being prisoners in enemy hands.

The outstanding lesson of the war is to be drawn from some figures collected by Colonel Soltan in France in 1917, figures which were corroborated again and again by all observers. The total admissions for sickness in one army during a year numbered 105,267; of these 26,879 were due to what were commonly called "skins and scabies,"—that is to say, 25 per cent. of the sick wastage was due to some form of pyoderma very largely preventable by careful inspection and personal cleanliness of the men. The corresponding figures for seven weeks observed in 1918 in another army by the reviewer varied between 18 and 24 per cent. in each week. In addition to the group "skins and scabies," there was a group consisting of pyrexia of uncertain origin, trench fever, myalgia, and rheumatism, which was undoubtedly composed in the main of cases of trench fever, and therefore louse-borne; that accounted for another 26,000 admissions, so that of all the casualties from sickness nearly 50 per cent. were attributable to dirt and vermin.

The editor-in-chief concludes that four great lessons may be learnt from the war:

1. The importance of uncleanliness must be recognized, and an army to be efficient must be kept clean.
2. The value of original research in the field must be realized; an efficient army must carry its medical research units with it.
3. The general staff ("G") must take wastage by sickness into account as much as wastage by wounds. An efficient army must have medical plans no less than military before embarking on a campaign.
4. Hospital treatment in the field must not be rough and ready; the clinical medicine and surgery of war time is susceptible of a high and exquisite perfection, and affords scope for the finest scientific work. In other words, an efficient army depends on its hospitals for reinforcements.

We wonder whether at the Staff College the value of guns and "delousers" is even now reckoned as being about equal. That shrewd old Scots law lord, Kames, remarked that "one cause of the aversion the English had to the Danes was their cleanliness; they combed their hair and put on a clean shirt once a week." We should not forget that the Englishman is extraordinarily conservative; let us hope, as Tennyson said that "we are each all Dane."

THE HISTORY OF BRAIN SURGERY.

SIR CHARLES BALLANCE has published as a book his Thomas Vicary lecture, *A Glimpse into the History of the Surgery of the Brain*.² This lecture has already appeared in condensed form in our columns, but no doubt many readers will take the opportunity now afforded them of reading this brief history in its extended form. Sir Charles Ballance writes with his accustomed erudition and wit becoming enthusiasm for the masters of bygone times. Beginning with the dawn of surgery in prehistoric times we come through Mesopotamia and Egypt to surgery in Greece, and from there by easy stages down to our own country and our own times. Brain surgery appears always to have excited interest, but, like the surgery of other regions, its history is rather the history of the application of certain general principles to a special region. These may have been, and indeed were, often merely fashions or modes of surgery; some have rested on sure foundations and have stood the test of time. This part of the text is illustrated by several diagrams of tools used in ancient times, among them a brace, bit, and burr of the sixteenth century, very similar to the Doyen instruments in common use to-day.

It is not by advances in the design and manufacture of instruments that surgery has reached its present state although from time to time an instrument is designed (such as the Albee saw) that gives greater possibilities that makes operating easier. For this reason it is not until recent times, when precise knowledge of pathological processes began to be understood and the doctrine of localization of function was appreciated, that brain surgery in its modern sense can be said to have made a beginning. It is true that surgical writings dating back almost to the dim mists of time refer almost without exception to injuries to the head, and also often to infections of the skull and brain.

¹ *The Medical History of the War Based on Official Documents: Diseases of the War*. Vol. I. Edited by Sir W. G. Macpherson, K.C.M.G., with the assistance of Sir W. P. Herrieham, K.C.M.G., Colonel T. R. E. Holt, C.B.E., D.S.O., F.R.S., and Lieut.-Colonel Andrew Balfour, G.B. O.M.G. London: H.M. Stationery Office, or through any bookseller. 1922. (Medium 8vo, pp. vii + 550; 5 coloured plates and other illustrations. £1 1s. net; post free £1 2s.)

² *A Glimpse into the History of the Surgery of the Brain*. The Thomas Vicary Lecture, delivered before the Royal College of Surgeons of England, December 8th, 1921. By Sir Charles Ballance, K.C.M.G., C.I. N.Y.O., M.S. Lond., F.R.C.S. London: Macmillan and Co., Ltd. 1922. (Demy 8vo, pp. 110; 39 figures. 10s. 6d. net.)

at interesting as these processes are, and far though we may be even to-day from a victory over them, we have reached more knowledge of these and of their treatment than we have, say, of tumours and of hydrocephalus. As we turn over the pages of this book we read of discoveries, often inexplicable neglect, and of rediscoveries; amplifications and amendments follow one another over the years in the manner with which all students of medical history are so familiar. There passes also before our eyes the great agent of names—men famous in their day, famous for all time in the pages of history.

The passages on the great discoverers of the past forty years will be read with the greatest interest. And we could wish that Sir Charles Ballance had expended more space upon them. We can only hope that he will do so in the future. He speaks nobly and loyally of the men of his own day—"And where is it possible to discover in all the world or in all time another group of names of Alpine altitude in urology such as our country can produce in Jackson, Chafer, Ferrier, Gowers, Sherrington, and Horsley?" At this point some of the younger men amongst us may be heard sigh for a Lytton Strachey to tell us more about them. But, great though the names of the last two generations undoubtedly are, there is still so much to learn and still so much to do that new names may prove themselves worthy to be written with those of the great past.

X-RAY DIAGNOSIS IN MEDICINE.

THE second edition of the treatise on the use of x-rays in clinical diagnosis by Professor ASSMANN of Leipzig has followed quickly on the first, which was reviewed in our columns on January 28th (p. 148). As he is in a position critically to survey the whole field and to write with considerable authority upon the interesting problems of diagnosis by x-ray examination when used in combination with other well-established methods, we propose now to give a somewhat fuller account of his views.

The book is very big and expensive, but as it is a reasoned piece of clinical work in the composition of which the x-ray examination has been employed to the full it deserves study.

The opening chapters are devoted to a consideration of the normal and morbid conditions of the heart. The technique is very well described, and the text is illustrated by diagrams and skiagrams which leave nothing to be desired in lucidity. The combination of anatomical drawings and tracings printed from the fluorescent screen image adds greatly to the value of the interpretation of the normal and morbid appearance. Merz and Groedel's work receives full appreciation, as does also the brilliant work of our French contemporaries Vaquez and Bordet. The chapter concludes with a reference to the blood vessels. A good example of arterio-sclerosis of the vessels of the leg shows how useful the x-ray examination may be.

An excellent section on the mediastinum and the lungs follows; then in order are reviewed the conditions met with in disease. Full consideration is given to the differential diagnosis of these conditions, and the x-ray appearances are described and illustrated by diagrams and excellent skiagrams. The various inflammatory lesions of the pleura are discussed and tumours of the lungs and chest are fully dealt with. An excellent chapter is devoted to the diaphragm. Special mention may be made of the records of tuberculous conditions; a number of good radiograms are given to illustrate the typical appearances. Tumours of the thorax are discussed at some length. A study of the part of the book dealing with the pathological conditions encountered in the region of the oesophagus will reveal the complexity of the subject and the practical difficulties encountered in diagnosis; the consideration of this important structure is always of importance, and the worker in radiology cannot fail to appreciate the value of an intimate acquaintance with the possible lesions and their significance when seen in the x-ray picture. Lesions of the oesophagus are well illustrated and the differential diagnostic points clearly set out.

The normal stomach and intestines are next discussed, and full description of the x-ray appearances in disease follows. The important lesions of the stomach and duodenum are exhaustively discussed, and what the author has to say on the diagnosis of gastric ulcer, hour-glass contraction of the

stomach, and new growths of that organ, provides profitable reading. The illustrations of a number of conditions commonly met with are good, and their value has been increased by the inclusion of a diagram placed opposite the skiagram; this plan brings out clearly the salient feature which leads to the diagnosis. This section contains a short article on the pancreas, its lesions, and their bearing upon gastro-intestinal diagnosis generally. The method of producing pneumoperitoneum is described and its value in diagnosis dealt with. The examination of the gall bladder is described and the diagnosis of gall stones briefly discussed. The urinary system receives scant attention, and the nervous system is also dismissed very briefly, although the diagnosis of intracranial lesions is dealt with and the sella turcica and pathological condition in it are well dealt with.

The book on the whole is good; much careful work has been given to its compilation, and an enormous amount of clinical material has been sifted in order to obtain the required diagnostic data. The author has brought to his aid a ripe experience in the study of internal diseases; this is obvious throughout the work, and amply proves that if the best is to be expected from x-ray examination a radiologist must have a full clinical experience. The illustrations have been carefully selected, are of high quality, and have been on the whole well produced. The book can be confidently recommended to all who are interested in the subject. Readers will, however, look in vain for any reference to British work. No doubt in following editions this fault will be remedied.

MERCHANT SEAMEN.

IN writing a book on the health and welfare of *Merchant Seamen's* Fleet Surgeon W. E. HOME, R.N., has been moved by a desire to place before the public the many hardships the men of the mercantile marine suffer and the many grievances under which they labour. The author, who has a considerable personal knowledge of the subject, displays great sympathy with the men; there is no doubt that in the smaller ships the state of things, even to-day, is often very bad and in most compares unfavourably with conditions existing in the Royal Navy. Though the views expressed in the book may be rather too sweeping, for the larger lines have very competent medical advisers and able medical officers, yet the fact remains that, of 10,000 ships on the British Register, less than 600 are required to carry a surgeon. In a paper on the health of seamen on board ship, communicated to the Section of State Medicine of the Royal Society of Medicine by Dr. Arnold Chaplin, medical inspector of the P. and O. Company, he observed that questions of hygiene were mostly subordinated by owners to other factors; and his insistence upon the desirability of subjecting all plans of new ships to a competent medical officer before construction was supported by Dr. Willoughby, medical officer of health for the Port of London. Dr. Chaplin also directed attention to the frequent absence of hospital accommodation and isolation wards. All these points are also insisted upon by Dr. Home. The position of the crews' living quarters is an open question, but those now provided in small ships are frequently abominable, and the ventilation inadequate. The very outspoken description of the conditions seen in some temporary cruisers during the war by Admiral Boyle Somerville, R.N., strongly supports Dr. Home's views. Many bills designed to improve the health conditions for seamen afloat have been introduced, but if anything effective is to be done the matter should, we think, be taken up by the Ministry of Health; in this connexion the constructive suggestions made by Sir Robert Hill, K.C.B., K.C.M.G., medical director-general of the navy, will be found of great value. The deplorable methods of recruiting seamen and of treating them when afloat which prevailed in the last century are giving way to more enlightened views, and it is being better recognized that even on financial grounds alone it pays to keep the men healthy, to provide them with amusements, rational treatment on board, and sailors' homes when on shore. Dr. Home's book is to be welcomed as a valuable contribution to the attainment of these objects. Much, however, remains to be done to arouse public opinion, and we welcome this book, which not only describes abuses but also suggests remedies. Statistics are at present very unreliable, and little comparison can be made with those of the Royal Navy, which starts with first-class lives.

Die Klinische Röntgendiagnostik der Inneren Erkrankungen. By Professor Dr. Herbert Assmann, Leipzig. Second revised edition. Leipzig: F. C. W. Vogel, 1922. (Imp. 8vo, pp. 735; 711 figures, 20 plates. s. 120s.)

Merchant Seamen, their Diseases and their Welfare Needs. By W. E. Home, O.B.E., M.D., D.P.H., M.R.C.P.S., Fleet Surgeon, Royal Navy. London: John Murray, 1922. (Cr. 8vo, pp. ix + 111. 5s. net.)

RURAL CHILD WELFARE IN AMERICA.

THE National Child Welfare Committee of the United States has been conducting an inquiry into rural child welfare, and the results are embodied in a volume* by eight contributors, published under the direction of EDWARD N. CLOPPER, Ph.D. The purpose, as stated in a prefatory note by the Secretary to the Committee, is twofold: to present a graphic picture of rural life in America so as to lead the public to realize the needs of country children; to trace the causes of defective conditions described and to suggest a preventive and remedial policy. The purpose is well fulfilled, and the several chapters fit into each other so as to present as complete a picture of child rural life in America as could be contained within the limits of the book.

The area selected for inquiry was Western Virginia. Many factors enter into the problem. The education of parents is often very defective. A coal mine operator told Dr. Clopper that he had hired 144 native-born white men living near his property and only 11 of them could sign the pay roll. That, however, was doubtless exceptional, as Mr. C. E. Gibbons, whose subject is the Rural Home, found that only about 20 per cent. could neither read nor write. The number of children engaged in agriculture nearly doubled between 1880 and 1890, and further increased by about a half in the next decade. The assumption that a country child living at home is ideally situated is held to be erroneous. It is well urged that a clear distinction is to be drawn between child labour and "children's work." A system of clubs has been instituted for promoting the latter, by development of head, hand, heart, and health, a four-leaved clover being the emblem of what is known as a Four H Club. Indifference to education, especially to school attendance, is manifested, not only by parents and children, but by the whole community. At the same time the standards for teaching are low, there is a shortage of teachers, and their scale of pay has been insufficient, though improvement is being made. Owing to sparsity of population there are a great number of small schools with only from ten to twenty pupils on the roll, and the school sessions are sometimes too short. Reform of these defects is pressed for in the chapter on the subject. Recreation is advocated in an eloquent chapter and the following statements are quoted from Wood:

"Children love play as all young beings love life, because life is play. The child's life is one of physical, mental, and moral development. Development means self-expression, self-expression means activity, and activity means play. Children do not play deliberately from ulterior motives; with them it is play for play's sake; play is life, they live to play; they are children because they play."

But the value of play is commonly not appreciated either by parents or farmers, and in a family poorly off a child's earnings count for much. But—and this will be unexpected by most readers—it is held that the common belief in the healthiness of farm work is hardly justified by facts. Muscular strength may be acquired, but there is little of the vigour of heart, lungs, or digestion, produced by exercise, and the boys and girls are apt to be round-shouldered and flat-chested. This, however, may be due to want of adequate play. An important chapter deals with dependency, neglect, and delinquency. It is indicated that much improvement is required in the organization of relief work where poverty and parental neglect are in question. Touching stories are told of the plight of tramp children from "broken homes" and of the failure of guardians to realize their responsibilities. Rural folk, however, show a warm hospitality towards homeless children, and kinsfolk are the first to receive them when separated from their parents. The causes and actualities of delinquency are discussed, and the relative action by the authorities concerned. The chapters devoted to taxation and to the State and the child are informative and suggestive. One item of what in this country we would call grandmotherly legislation may be quoted.

"It is a crime to sell or give to any child under 21 years of age any cigarettes or cigarette paper, or to sell, give, or furnish tobacco in any form to a child under 16 years of age, or for any child under 21 years of age to make or have cigarettes or cigarette paper; and it is made a part of the duty of all peace officers to enforce this law against the use of cigarettes."

Prohibition in the States is clearly not confined to the use of alcohol, and the great democracy has no hesitation in interfering with individual liberty where the interference is regarded as for the public good.

**Rural Child Welfare*. Issued under the direction of E. N. Clopper, Ph.D. New York: The Macmillan Co. 1922. (Cr. 8vo, pp. 255; illustrated, 14s. net.)

The whole book is packed with material alike interesting and valuable to all who are concerned with the broad principles of child welfare as they apply to rural areas; and the committee responsible for the volume is to be congratulated on the outcome of its labours.

NOTES ON BOOKS.

A REVISED edition (the ninth) has appeared of the popular little *Aids to Forensic Medicine*,⁶ originally written by Dr. WILLIAM MURRELL, physician to the Westminster Hospital, and since his death edited by Dr. W. G. AITCHISON ROBERTSON, lecturer on forensic medicine in the Extra-Mural School of Medicine, Edinburgh. In its new form the work will no doubt prove as useful to students preparing for examination as it has in the past. Among the added matter is a paragraph briefly summarizing the medical requirements imposed by the regulations under the Dangerous Drugs Act, 1920. There is also a note on the Proprietary Medicines Bill, which was introduced by the Government two years ago, and is (in Dr. Robertson's optimistic view) "likely soon to become law." The paragraph on professional privilege in courts of law (p. 8) is as concise as it is unemotional.

A pamphlet of forty pages, entitled *Four Sanatorium Lectures*, has been prepared by Dr. H. O. BLANFORD for the use of patients who are undergoing a course of sanatorium treatment at Midhurst, and the author hopes it may be welcomed by a wider public. The rationale of the routine is explained, the system of graduated exercise described, and advice with regard to the ordering of home life after leaving is proffered. The aim throughout is to enlist the intelligent co-operation of the patient, and to induce him to view his trial with equanimity and hope. We would offer him one word of criticism. The dietum is very forcibly laid down that in pulmonary tuberculosis "the only vehicle of infection is sputum, which contains the tubercle bacillus." Now, however advisable it may be to stress the infectivity of the sputum, it is useless to do so without at the same time laying emphasis on the dangerous nature of the cough spray which accompanies the expectoration of that sputum. If there is one thing which bacteriology has shown clearly during the past few years it is the importance of spray infection in the spread of respiratory diseases; and to allow a patient to cough and sneeze promiscuously without a handkerchief in front of his mouth—as actually occurs at some of the best sanatoriums—is to give him a poor education in his duties to the public with whom he is subsequently to come in contact. If a further edition of this useful booklet should be called for the author might well correct the unduly large number of spelling mistakes and misprints which somewhat mar his first effort.

It is now nearly twenty years since the late RAKHALDAS GHOSH published the first edition of his *Treatise on Materia Medica and Therapeutics*.⁷ In designing this wonderfully compendious little book the author, we believe, had sympathetic encouragement from the late Sir Pardee Lankis. Its appreciation by students and practitioners is proved by its recent issue of a ninth edition. The contents have been revised throughout by the present editors, Lieut.-Colonel B. H. Deare and Dr. B. N. Ghosh, and various minor changes in arrangement have been made; but the size of the volume has only been increased by three pages since the eighth edition appeared two years ago. This work remains one of the most useful and practical of the smaller reference books on the properties, actions, and uses of medicinal preparations.

Professor SOLLMANN of Cleveland has issued a second edition of his *Manual of Pharmacology*.⁸ Since the first edition, which was reviewed in our columns on December 29th, 1917, much work has been done, but, as the author admits in his preface, there has not yet been time thoroughly to digest all the material. He has, however, found it possible to make many additions and corrections. The sections on irritant gases have been expanded by the introduction of references to their use in the war. A useful feature of the book is a bibliography occupying 79 pages; it has been enlarged in this edition by the addition of over 1,200 titles.

⁶ *Aids to Forensic Medicine and Toxicology*. By W. G. Aitchison Robertson, M.D., D.Sc., F.R.C.P.E. Ninth edition. London: Baillière, Tindall, and Cox. 1922. (Fcap. 8vo, pp. xii + 155. 3s. 6d. net.)
⁷ *Treatise on Materia Medica and Therapeutics*. By Rakhaldas Ghosh, M.B., B.S., and Birendra Nath Ghosh, F.R.C.P.S. Calcutta: Hilton and Co. London: Simpkin, Marshall, and Co., Ltd. 1922. (Cr. 8vo; pp. 712. 10s. 6d.)
⁸ *A Manual of Pharmacology and its Applications to Therapeutics and Toxicology*. By Torald Sollmann, M.D. Second edition. Entirely reset. Philadelphia and London: W. B. Saunders Company. 1922. (Roy. 8vo, pp. 1065; 29 figures. 32s. 6d. net.)

Miss MARY B. EYRE, who is President of the Colorado Board of Nurse Examiners, has written a volume, *Psychology and Mental Hygiene for Nurses*,⁹ which should be useful to the increasing number of nurses engaged in public health and welfare work. Such work takes the nurse into the homes of the people, and the author feels that an understanding of the principles of psychology and its application will greatly extend her sphere of influence. The book provides an elementary but systematic account of general psychology, the psychology of childhood, the subconscious mind and the forces which determine human behaviour, and the principles of mental hygiene in relation to nursing. Each chapter includes a useful summary of its contents, and the subject-matter is presented throughout with commendable clearness.

The *Durham University Calendar*¹⁰ for the year 1922-23 has just been issued; the general arrangement follows the plan adopted in previous years. Full information is given regarding the University of Durham College of Medicine at Newcastle-on-Tyne, and the rules for students attending the Royal Victoria Infirmary are set out.

⁹ *Psychology and Mental Hygiene for Nurses*. By Mary B. Eyre, R.N. New York: The Macmillan Company. 1922. (Cr. 8vo, pp. 203; 9 figures. 7s. net.)

¹⁰ Newcastle-on-Tyne: Andrew Reid and Co., Ltd. 1922. (Cr. 8vo, pp. 756. 3s. 6d. net; by post 4s. 3d.)

Nova et Vetera.

"THE ENGLISH SPAW" AND "THE COLDE SPRING OF KINGHORNE CRAIG."

Up to the close of the sixteenth century the term "Spa" was given solely to the little town to the south-east of Liège in the Ardennes, where people went to drink the waters of the Poulhon, La Sauvenière, and the other springs. In the next century, however, the word "spa" began to be used in a generalized sense of a medicinal or mineral spring anywhere; and Dr. Timothy Bright (1551-1615) did something to extend its employment in this way by naming the Trowhit Well at Harrogate, in the Forest of Knaresborough, "the English Spa." The well had been discovered about 1571 by a Mr. William Slingsby, who had travelled abroad and known the taste of the fountains at Spa; he did "drink the water every yeare after all his life time," and was of opinion that "it was much better, and did exceed the tart fountains beyond the seas." With such a treasure in our own Yorkshire, said Dr. Bright, why go to the "German Spaw"?

Others were of the same opinion; and so, in 1626, Dr. Edmund Deane of York wrote his little book¹ called *Spadacrene Anglica*, or *The English Spaw Fountaine*, a short review of which was published in the *Journal* of August 12th (p. 272). In the preface, "to the physicians of Yorke," Deane wrote: "Though it was my fortune first of all to set a new edge on this businesse; yet my journeyes to this Fontaine have not been made without your good companies and association, nor the several tryals had there, and at home performed without your worldly helpes and assistance; nor this little Treatise begun without your instigations and incitements."

Of one of these "journeyes" with Deane to the Well, Michael Stanhope gave a partly humorous account in his *News out of Yorkshire*, published in the same year (1626) as the *Spadacrene Anglica*. There were three "physitians"; Stanhope was enthusiastic: "first of all I dranke of it and finding it to have a perfect Spa relish (I confesse) I could not contain but in a tone louder than ordinary I had them welcome to the Spa." The "physitians," on experiment bent, mixed in a glass the powder of galls with the water to see if it would "turne to a Claret die"; "wherein they were not deceived, for presently (to their both wonder and joy) the water changed colour and seemed to blush in behalfe of the Country, who had amongst them so great a jewell and made no reckoning of it."

Deane's book is the first work on the waters of Harrogate. It passed through four editions, all of them now very rare, and the profession is indebted to Dr. James Rutherford for reprinting in this present year the first of them, that of 1626, and to Dr. Alexander Butler for supplying biographical notes. The reprint is welcome also because it corrects some errors

¹ *Spadacrene Anglica, or The English Spa Fountaine*. By Edmund Deane, M.D. Oxon. The First Work on the Waters of Harrogate. Reprinted with Introduction by James Rutherford, L.R.C.P. Ed., and Biographical Notes by Alex. Butler, M.B. Bristol: John Wright and Sons, Ltd. 1922. (p. 115 6s. net.)

which have crept into the story of early days at Harrogate when that place was a mere hamlet in the Royal Forest of Knaresborough. Among these was the statement that the discoverer of the well was Sir William Slingsby. It was really his uncle, Mr. William Slingsby, born in 1526 or thereby, to whom this honour must be given. Deane's book was published in 1626, so was Stanhope's *News*, whilst Slingsby's birth was in 1526; so here are two tricenarians and one quatercentenary rapidly approaching, and Dr. Rutherford's reprint prepares the way for their fit celebration some four years hence at "The English Spaw."

The Tuit or Trowhit well at Harrogate was so called, Stanhope thought, "forne other cause but that those lirdes (being our greene Plover) do usually haunt the place." The water was chalybeate, like that at the German Spa; and Deane enumerated a long list of maladies in which it worked wonders. It was, for instance, of much profit "in the inveterat venereous Gonorrhoea"; it cured sterility and the tendency to miscarriage, but curiously enough it was not to be used by expectant mothers; it was efficacious in worms, killing and expelling them, and letting and hindering the breeding and "new oncrease of any mooe;" it was "very available" against the stone in the kidneys; and it helped the black and yellow jaundice, and "the evil which is accompanied with strange feare and excessive sadness without any evident occasion, or necessary cause, called *Melancholia Hypochondriaca*." The waters, however, were not to be taken without the advice of the physician, for this reason: "Medicines are not said to be *Deorum manus*, that is the hands of the Gods . . . or *Deorum dona*, that is the gifts of the Gods . . . till they be fitly applied and seasonably administered by the counsell and advice of the learned and skillfull Physitian." For instance, there were those who thought it dangerous to take purgatives and the water of the well in the Dogge-dayes; the same opinion was held about blood-letting. Deane wrote that there was here an old and inveterate error, "which in all probability hath cost mee Englishmens lives, thon would furnish a royall army, in . . . great helpes or remedies, to wit, Purg- . . . in hot seasons of the yeare, which in . . . have saved many of their lives; while expecting more temperate weather, they have bene summoned in the meane time, or *interim*, by the messenger of pale death to appeare in an other world." Wherefore, concludes Deane, away henceforth with the scrupulous conceit and too nice fear of the Dog-dayes.

Deane's *Spadacrene Anglica*, therefore, was an early work on mineral waters in Great Britain; but there was an earlier, for in 1618 Patrik Anderson, "Doctor of Physick," published in Edinburgh *The Colde Spring of Kinghorne Craig* (in Fife), his admirable and new tryed properties, so far forth as yet are found true by Experience. Of this rare pamphlet there is a copy in the library of the Royal College of Physicians in Edinburgh. It was dedicated to "the Right Noble and Illustrious Lord, Johnne Erle of Mar, . . . Lord High Thesaurer of Scotland, Knight of the most noble order of the Garter, and one of his Maiesties most honorable Privie Counsell, of both Kingdomes"; and the author generously wished to the noble Lord and his most noble Ladie "a great portion of Methusalems yeeres for this lyfe, and, after it, eternall life."

There is much that is of interest in the pamphlet (something may be extracted from it again); it shows "the craig" itself, which is thus located: "hard by the shore syde of Kinghorne, within a bow draught or more to the heaven of Pretic-cur where the Botes arrive, direct west the Sands, is a great round steip Rock." Anderson, like Deane, enumerates many things for which this "fair spring (albeit but litle knowne)" was useful; and he addresses his readers—"Goe thon with boldnesse, and drinke of this wholesome and Physicall water, and say not to yourselfs, the Physitians envyeeth it, speaketh against it, they approve it not, and it hindereth their gaine; onlie but carie with you these few directions following, and so faire yee well." Some of the directions are like those for the *Spadacrene Anglica*, but there was at least one special injunction, the swallowing of eight or nine of the author's *grana angelica*, "hid in a rere [that is, half-cooked] or potted egg." Both the Fifeshire and the Yorkshire spas were famous in the early part of the seventeenth century; but a very different fate has befallen the cold well at Kinghorn when contrasted with that of the Trowhit Spring at Harrogate. Groom's *Ordnance Gazetteer of Scotland* (1901) has this sentence, "the medicinal well has now for many years fallen into neglect."

British Medical Journal.

SATURDAY, OCTOBER 14TH, 1922.

RADIATIONS IN GYNAECOLOGY.

THE paper in which Dr. Robert Knox introduced the discussion on the treatment of gynaecological conditions by *x* rays and radium in the Section of Obstetrics and Gynaecology at the Annual Meeting of the British Medical Association in Glasgow is published this week (p. 678). It was an able and quite impartial address, and led to a brief but very interesting discussion.

Putting aside the smaller things, the main points in the discussion related to malignant disease and fibroids: should radiation treatment be used for these conditions in preference to surgical? The opener laid down the principle, with some degree of emphasis, that "in all cases which are suitable for surgery, surgery should be recommended." The general consensus of opinion with respect to fibroid disease also was evidently in favour of operation, reserving *x*-ray treatment for cases in which for one reason or another operative treatment was inadvisable. With this opinion we will not quarrel, but at the same time it should be remembered that it is not universally accepted, and that men like Bécclère of Paris, whose experience is very large, publish long lists of cases treated safely and successfully with *x* rays.

The real subject under discussion, however, was the question of radiation treatment in malignant disease of the cervix and uterus, and the prominence which has of late been given to this subject by the claims of the Erlangen school. At once a difficulty arises, for in this country, at any rate, the cases so far allocated to both radium and *x*-ray treatment, singly or combined, have been those which have reached the stage in which they have been pronounced to be inoperable. In Bavaria, on the other hand, many cases in the operable stage—which of course is an earlier stage of the disease—have been selected for *x*-ray treatment. It follows that statistics and results are not comparable. The question arises whether, with the increasing evidence of beneficial results in inoperable conditions, we are not reaching the stage when the position as between the knife and radiations should be impartially considered at a much earlier stage of the disease. Can there be any doubt that in many respects the knife as a cure for cancer—uterine or otherwise—is a ghastly failure? Those in charge of *x*-ray departments of large hospitals for the last fifteen or twenty years have had an experience in which the failure of operations has been brought home to them in no uncertain manner. Breast carcinoma, which on the face of it, from early diagnosis, visibility, ease of access, and so on, should lend itself to operation, and should furnish results more favourable than more deeply seated malignant disease, is not pleasant to contemplate from the point of view of the radiologist as he sees the late after-results sent to his department as "a last hope." This being the case, what can be said for the operative treatment of the more deeply seated, more inaccessible, and probably less early diagnosed growth?

There can be no doubt that the work of Wintz and Seitz has given a great stimulus to *x*-ray therapy, and it is possible that in the future it may lead to still further developments. The whole technique has been placed on much firmer ground than hitherto, and this is especially the case as regards dosage; but much more than this has been claimed, and a definite lethal *x*-ray dose for various conditions, and especially for the cancer cell, has

been stated. That this position cannot be maintained is now becoming obvious, for if there is a definite lethal dose for the cancer cell then the cure of cancer, or at any rate of the primary cancer manifestation, should be a mathematical certainty. This is far from being the case unfortunately, and it is recognized on all hands that many other factors—for instance, the character of the cancer itself, to say nothing of its host—have a considerable bearing upon the assertion. It has also been laid down as an axiom that there is such a dose as a stimulating dose for the cancer cell. Actual proof of this from a clinical, and not a laboratory, point of view has not been established; every radiologist has seen secondary cancer nodules disappear rapidly and entirely after receiving what Wintz and Seitz state to be stimulating doses. The problem is not quite so simple as all this.

Dr. Knox asserts positively that the statistics which have been published on *x*-ray treatment in carcinoma of the cervix do not encourage us to support the claims in favour of *x* rays as against those of surgery. This, unfortunately, appears to be a principle from which we cannot depart, at any rate at present, and it means that radiation treatment must still be restricted to the inoperable condition. An important fact which should not be overlooked is that, notwithstanding the original claims of success in the *x*-ray treatment of cancer of the cervix, Wintz has considerably modified his technique, inasmuch as he now resorts to a long preliminary ionization of the growth before proceeding to administer the lethal *x*-ray dose. Further, many other workers consider that the primary growth should be treated by the introduction of radium needles, again as an adjunct to the large measured *x*-ray dose; Dr. Knox himself is strongly in favour of the plan. These facts go to show that we are still far from having perfected that ideal method of *x*-ray treatment which was heralded with much beating of drums and blowing of trumpets so short a time ago. It should also be remembered that, after all, *x*-ray treatment and surgery aim at the same thing—namely, the removal of the primary growth and the treatment of the adjacent lymphatics and glands likely to be affected. Neither, in any way, attempts, or can attempt, to deal with the still greater problem—namely, the prevention of distant metastases. What if it should turn out that in the large majority of cases, by the time the primary manifestation has become evident, the disease has already become a generalized condition, and that only some resistance, with which we are at present unacquainted, prevents the metastatic growths from appearing almost at once; that once infected, at any time, on this resistance breaking down generally or locally, general or local recurrence may occur, and this at any period of time after an operation, be it by the knife or by radiation? To put a fixed time, even five years, and say that if patients survive that time after the removal of a primary growth without recurrence they are cured is not logical. Perhaps we may more rightly say that a case once recognized is never cured, and that the potentialities of a recurrence, locally or in the metastatic form, are always present. Then if the patient dies of something else before recurrence takes place he has been cured; if, on the other hand, he lives long enough, recurrence would seem to be almost inevitable. The cure of cancer and malignant growths generally can only follow, if it does follow, on a complete knowledge of the cause and life history of the disease, and this cure will not mean merely dealing with a primary growth and its immediate surroundings.

The cost of *x*-ray treatment was alluded to by some of the speakers, and the opinion was expressed that the great drawback to radiation treatment generally was that it was so expensive. The obvious reply to this criticism would be to compare its cost with that of surgery. The cost of effective radiation treatment ought

not to be, and is not, as great as that of a major surgical operation, which by no means comes to an end with the fee of the operating surgeon. X-ray treatment does not mean a lengthy stay in an expensive nursing home, the fees of nurses for many weeks, and so on. If a case is operable, expense does not stand in the way of operation. If a case is pronounced inoperable and radiation treatment can hold out reasonable hopes of a prolongation of life under conditions which make it worth while to the patient, then the fees usually paid can hardly be said to be excessive. Skilled radiologists, competent to carry out the modern treatment of cancer by x rays, are at the present time few, very few, in number. It takes anything up to six or eight hours to treat a case of cancer of the cervix, and practically the private practitioner has to give the one case his personal attention for this length of time. Would a surgeon be content with the fee he now gets for a similar length of service? Moreover, the radiologist has to use apparatus which costs about £1,000, and apart from this his running expenses are at least as great as those of a surgeon. No, the cost is not excessive, and if the time comes (and it may possibly come very soon) when radiation is found to be preferable to surgery for the treatment of many primary growths, the patient will stand to gain pecuniarily rather than lose, if everything is taken into consideration. A far more important point than expense is choice of operator. A very large number of the profession, and the public generally, seem to consider the possession of apparatus the sole qualification for successful and safe x-ray work. It is in this direction that a word of warning has become essential. It is not too much to say that the choice of a radiologist to carry out treatment in these life and death cases should be made with at least as much care as when an operating surgeon has to be chosen.

THE WASTAGE OF CHILD LIFE.

THE September issue of the *Glasgow Medical Journal* contains a valuable study of mortality rates in Glasgow families by Miss Jean Agnew, working under a grant from the Medical Research Council. The article has an introduction by Dr. Leonard Findlay. The material used is from two sources: one, the histories of 1,768 poor families as medically recorded at the Royal Hospital for Sick Children (the fine institution visited by many members of the British Medical Association during the recent Annual Meeting in Glasgow); the other, the figures relating to 455 well-to-do families, taken from the private case records of a consulting paediatrist. In the poor families the total number of pregnancies was 9,763, which, including stillbirths and twin-births, yielded 9,954 "possible" lives, the average family therefore consisting of 5.6 possible lives. The corresponding figures for the well-to-do families were 1,440 possible lives, or an average of 3.2 per family.¹ These are the data on which the calculations and the classification of types of wastage are based.

As charted, it appears that in respect of miscarriages and stillbirths the well-to-do families are no better off than the poor families. In fact, if these data are to be relied on, the wastage is slightly higher in the former. If practical equality in this respect were established on a sufficient basis of fact it would tend to show that at the beginning of life the poorly-off mother is just as safe a child-bearer as the mother in comfortable circumstances. Also the difference in favour of the well-to-do class shows only very slightly in the first month of life, so that the baby of poor parents seems as healthy as the

baby of parents who are better off. But before the end of the first year the difference is very apparent, and becomes much more obvious later on when all deaths are compared. Also the disadvantage of the poorer families is greatly magnified when pregnancy succeeds pregnancy, as shown by the increase in the infantile death rate. This does not take place in the larger families of the prosperous, who are able to give as much care and attention to children born later in wedlock as to the earlier births. There is, however, a curious reservation here, arising from one chart relating to the richer families, which seems to indicate that "the best chance of survival lies with the result of the third pregnancy." The reader may ask himself, What can be the explanation if this be really so? Can it be that skill in mothercraft has by that time improved, so that risks to which the first and second babies may have been unwittingly exposed are avoided in the case of the third? But if so, why should not the fourth be still better guarded? Is it possible that, the average well-to-do family being 3.2, the fourth and later pregnancies, where they occur, are somehow under less favourable conditions, say, as to the age and health of the mother? The average age at marriage in the middle class is certainly higher than among the poor, and the optimum time for child-bearing may have been reached in the third pregnancy. That, however, is highly speculative.

Miss Agnew attributes the bad record of the poorer families to increased overcrowding, lessened outlay on food per head (at least until the older children become wage-earners), lessened maternal care, lessened cleanliness, and the like. Some of the charts show the results in the poorer families up to twenty pregnancies, and a comparison of New York data with those of Glasgow brings out a remarkable similarity. The last paragraph of her report is as follows: "From among much that is suggestive, one fact that is definite emerges. In the large poor families—no figures are available for well-to-do families of similar size—probably from the fifth, and certainly from the seventh pregnancy, the wastage is so great as to indicate that—be the cause what it may—the additional members of the family are bought at a cost in human life and suffering which cannot be regarded as equitable, whether viewed from an economic or from a humanitarian standpoint."

SHORTAGE OR OVERCROWDING?

It was with some surprise that we read last week the following passage in a leading article in a London daily newspaper on the reopening of the medical schools: "We are glad to learn that the profession is attracting young men and women in greater numbers than of late, but something has yet to be done before the schools can muster as many students as before the war. That the nation needs more is sufficiently obvious. The natural increase of population alone would call for more practitioners. . . . That the war and the sequel of the war should have diminished the numbers of recruits was inevitable." This is not accurate; in fact, it is almost the opposite of the truth, as may be recognized by anyone who has studied the figures given in our Educational Number of September 2nd. The fact is, of course, that there was a great increase in the numbers of medical students during the war and a much greater increase after the armistice. In 1919 the new students who registered in Great Britain and Ireland numbered 1,100 more than the "record" entry of 1891. In 1920 the entrants were still greatly in excess of any pre-war year, and it was only in 1921 that the number of new students began to approach the normal. During the thirteen years before the war the annual entry of first-year medical students in the United Kingdom averaged 1,400; in 1921 the number was 1,808. In consequence of the great numerical increase in the student body during and after the war many of the schools throughout the country

¹ Table I the two percentages seem to have been accidentally transposed and appear at the head of the wrong columns.

became overcrowded, and some were obliged to turn away applicants. It is a mistake, therefore, to say that "something has yet to be done before the schools can muster as many students as before the war." On the contrary, the recent fall in the entries has been a great relief to the overstrained teaching institutions. Nor is it by any means obvious that "the natural increase of population calls for more practitioners"; the general tendency through the past forty-five years has been towards an increase in the ratio of doctors to population. While the population of Great Britain and Ireland has increased by about 50 per cent. during that time, the number of registered practitioners has been doubled. In view of all these facts, it is plainly undesirable to suggest to the public that there is a shortage of recruits for the medical profession. Indeed, the number of new students has been so excessive in recent years that, had the torrent not been stemmed last year, there was a certainty that within a short time the profession would be seriously overcrowded. The return to a more normal entry has therefore been welcomed, not only by the overburdened schools, but by those who, like ourselves, felt apprehensive lest there should not be work enough to go round when the present generation of students become qualified.

PUBLIC HEALTH IN PALESTINE.

WERE the English given to self-praise rather than to criticism they might dwell with no little satisfaction on the excellent results of those public health measures against infectious disease which depend mainly upon British organization and executive in the Near East. By the courtesy of the Director we have before us a copy of the first annual report (1921) of the Department of Health under the Government of Palestine. It is a very modest document, not in print, but in multigraph; the achievements recorded in it, however, are well worthy of notice. It gives a concise account of the building up from the beginning of a medical and of a health service in a country ravaged by war and decimated by disease. Under the Ottoman rule a skeleton of a medical service existed in theory, which, had it been adopted in practice, might have sufficed for the primary needs of the country. In voluntary organizations, however, the country was comparatively rich, and the report fully recognizes the admirable work done by them in the early days of the new Government. The Syria and Palestine Relief Society, the American Zionist Medical Unit, and the American Red Cross, in their respective spheres, organized hospitals, clinics, and relief. In 1919 and 1920 the old-established charities such as the Church Missionary Society, the Scottish Mission, the Hospitals of the Order of St. John, the American Zionist Unit, and the French Religious Hospitals were reopened, and are now in full working order in spite of the ransacking of their equipment and in several instances the ruin of their buildings during the earlier years of the war. To a large extent they relieved the Government of its responsibility by providing accommodation for the country's sick in general, as distinct from Government employees and patients with infectious diseases. The Government hospitals number eleven and contain three hundred and seventy-two beds; the voluntary hospitals, which number twenty-three, provide nearly a thousand beds. There are five smaller voluntary special hospitals and thirty-one dispensaries. The proportion of hospital beds thus appears to be 1 to 536 of population, a very creditable figure. The general directorate or central organization of the Department of Health is divided into five sections. The first deals with public health and epidemics. It includes a sanitary engineering subsection which deals with antimalarial projects and co-ordinates the sanitary projects with public works. In a land where water supplies are unsatisfactory and insufficient, where town drainage is practically non-existent, and where antimalarial drainage of swamp areas is perhaps the first sanitary need, the importance of this section need not be emphasized. The second section of the directorate deals with medical and hospital organization, an important

subsection dealing with ophthalmic hospitals, ophthalmic treatment of school children, and special surgery. The third section controls bacteriological, analytical, and entomological laboratories. There is a central bacteriological laboratory at Haifa and four Government clinical laboratories in Jerusalem and other towns. The fourth section directs the quarantine service, including relief, lunacy, and railway sanitation. The work of the quarantine service has become each year more exacting. The fifth section deals with medical stores. The local health administration is under principal medical officers of health, who are responsible for medical, health, and quarantine services within their district. Under them are district medical officers and hospital and quarantine medical officers, under whom again are sanitary, antimalarial, and quarantine subinspectors, disinfecting and nursing staff. Development has been hindered by the smallness of the credits available, but the nucleus of each essential service now exists and can be expanded as financial conditions allow. The administration has thought ahead and has adopted a programme which will in any case take several years to realize. The most important projects include the extension of the antimalarial campaign to include the reclamation of marshes, public water supplies in the larger towns and villages, main drainage in the more important towns where water supply is established, additional accommodation for the treatment of trachoma and for the development of scavenging services. Great importance is attached to the training of midwives, there being at present only 51 trained midwives in Palestine. Malaria has decimated the population for centuries, and whilst the measures taken in populous areas to destroy and prevent the breeding of mosquitos in the innumerable rock cisterns, the treatment of infected persons, and educational work dealing with the nature and prevention of the disease are of great value, they cannot attain full success while the marshes continue to be great anopheles reserves. Successful Government schemes have been carried through in the Beisan and Jenin marshes, and private enterprise has been encouraged wherever possible; as in the Wadi Gazazo, at Musherifa, and in the Kinnareth marshes. To give some idea of the amount of work done apart from the draining of swamps we may mention that during 1921 sixty-six thousand possible breeding places—wells, cisterns, and cesspits—were recorded and registered; sixteen thousand of these were made mosquito-proof by closure or covering, and eleven hundred by fitting pumps; oiling was carried out on nearly two-thirds of a million occasions in those places which could not be rendered mosquito-proof, seventy-six tons of paraffin and crude oil being used. Householders neglecting to carry out precautions after warning were prosecuted in 702 instances. Trachoma is the second great plague of Palestine; it is estimated that 74 per cent. of school children are infected. The amount of work and organization necessary to combat this disease and its sequelae is gigantic. Most creditable to the sanitary and quarantine administration is the lowness of the general incidence of infectious disease, especially considering the geographical situation of Palestine. No case of cholera, only 4 cases of plague, one small outbreak of smallpox with only one fatal case, 63 cases of typhus fever with six deaths, 368 cases of typhoid fever with a case mortality of 9 per cent., and 91 cases of paratyphoid with a case mortality of 3 per cent., make a remarkably low record. Rabies is very prevalent amongst the dogs and hyenas; and 455 patients received antirabic treatment in the Pasteur Institute of Jerusalem during the year. British preventive medicine may well be proud of her latest offspring.

THE TRAINING OF THE PHARMACIST.

ON October 4th the School of Pharmacy of the Pharmaceutical Society of Great Britain entered upon its eighty-first session. The ceremony took place in the Society's examination hall in Bloomsbury Square. In his opening speech the President (Mr. E. T. Neathercoat) remarked that pharmaceutical training was in a state of transition at the present

moment, and the Council was giving this matter their closest attention; and the Dean (Professor Greenish), in his report on the year's work, welcomed the prospect that in the very near future the time given to the student's training would be materially extended. The twofold function of modern pharmacy—research and education—has been emphasized by the award this year of the Haubury medal to Professor Émile Perrot, who has made important investigations into the stabilization of vegetable drugs, and holds the office of Vice-Dean of the Faculty of Pharmacy in the University of Paris and professor of materia medica. The President, in presenting the medal and welcoming Professor Perrot, mentioned that he was the fourth distinguished Frenchman to receive this award. The inaugural sessional address was delivered by Mr. H. J. Waring, F.R.C.S., Vice-Chancellor of the University of London, and here again education was kept in the foreground. His subject was the advantages (and the drawbacks) of a university training for a technical vocation such as pharmacy. His method of approach was to sketch the main outlines of a university course in the basic subjects of a vocational curriculum. For the technical vocations of pharmaceutical chemistry and pharmacy he thought it would be an advantage if all students underwent a scientific training comparable with that which was now regarded as necessary for industrial chemistry, engineering, and medicine; and he urged the need for some instruction in the principles of biology, so that the pharmacist should understand thoroughly the practical part of his science. Another advantage of a university course was that it enabled the student or practitioner to carry out with intelligence original investigations in his own subject and so promote the advancement of his vocation. But Mr. Waring recognized that all students were not alike; some who could readily learn all the mechanical parts of their profession had not the intellect to grasp the theoretical parts, and it was far better that they should not attempt a university or college education.* He had long held the view that pharmacy was worthy of a higher position among the technical vocations, and for this reason he welcomed the news that the standard of the entrance examination for the School of Pharmacy was likely to be raised. A higher level of preliminary general education was needed if all the advantages of a scientific training were to be gained. It had been suggested that a closer connexion with the University of London by the Pharmaceutical Society would have a beneficial effect on pharmaceutical chemistry and pharmacy. In general principle this appeared correct, and if the Pharmaceutical Society brought forward a concrete scheme in which they asked that either pharmaceutical chemistry should be made the chief subject for a science degree or that a new degree, such as Bachelor of Pharmacy, should be instituted, the University would explore the whole question and try to meet the Society in every way, provided that whatever was done was for the progress of science, the good of the nation, and the improvement of the vocation.

PRINCESS MARY INFANTS' WARD AT LEEDS.

THE General Infirmary at Leeds contains within its walls, as everyone who is conversant with its working knows, a fully equipped children's hospital. The tendency of the great Leeds charities has been towards centralization and not to the multiplication of small institutions. The management is fully alive to the desirability of segregating those of tender years and of securing facilities for the early removal to suitable extensions of the hospital in the country of patients who have been subjected to operations or have suffered from medical complaints as soon as this is deemed wise. The rearrangement of beds throughout the hospital, which was commented upon in this column some months ago, has secured this segregation by the allotment of three large wards (Nos. 6, 8, and 10) for children. Each has accommodation for thirty-three patients, and it is expected that this accommodation will be increased by the provision of a certain

number of cots in an open-air ward on part of the north terrace. On the surgical side of the house the patients are dealt with by the ordinary surgical staff; on the medical side, some two years ago, special arrangements were made. It was arranged that one member of the staff, Dr. Vining, who at that time was junior assistant physician, should in his infirmary work confine his attention to the subject of the diseases of children. He had his out-patient clinics, and to him was allotted all the cots which were, or in future might be, devoted to the care of infants under the age of 3 years who were suffering from nutritional diseases. This class of patient was specially considered, as it was felt that a great work was awaiting development in connexion with infant welfare. Already Dr. Vining's work has borne fruit—directly by the increased attention that this class of patient receives, and indirectly by the improvement of the teaching of students. Dr. Vining's work is not confined to children of this age, for he has out-patient clinics for children up to 10 years of age, and to him are allotted a proportion of the cots for children up to that age. The institution of this special department for children is regarded as a step in the right direction and as one that will prove to be free from some of the disadvantages of special hospitals. It is in connexion with this development of the work of the Infirmary that the opening of the Princess Mary Ward for Infants has been so very cordially welcomed. At the suggestion of the Lord Mayor, the Princess was graciously pleased to allow the wedding present which Leeds desired to present to her to take the form of this ward to be added to the Infirmary. Large donations were not solicited, and it is especially pleasing to learn from the speech of the Lord Mayor, when he was requesting the Princess to declare the ward open, that some 40,000 of the school children of Leeds had added their mite to the £5,000 which had been contributed. The ceremony of opening the ward was performed by the Princess, who, along with Viscount Lascelles and the Countess of Harwood, visited the Infirmary on October 2nd; the weather was fine, and the reception accorded to Her Royal Highness was most cordial. Admission to the Infirmary was granted to as many as it was possible to accommodate along the course which was followed by the Princess, who, after some presentations had been made, was conducted to the new ward by Mr. T. L. Taylor. Here the Lord Mayor read an address, and asked the Princess to open the ward with the key which was presented to her by Mr. Sydney Kitsen, the architect of the new ward. Having done so and declared the ward open, Princess Mary made a full inspection of the ward and of its annexes under the guidance of Mr. T. L. Taylor, who had, in a few well-chosen words, thanked the Princess for her generous gift. Old students will be interested to know that the new ward occupies the space between the staircases of No. 6 and No. 8 wards, largely above the clinical lecture theatre. Access to it is from the north terrace and also in connexion with the landing of No. 8 ward. It is self-contained, and has lavatories and kitchen of its own. There is accommodation for some twelve or fourteen cots for infants. Dr. Vining will be in sole charge of this ward, and its provision will enable him to develop this part of his work on good lines.

THE QUEEN ALEXANDRA SANATORIUM FUND AT DAVOS.

WE have had several inquiries in recent years about the fate of the Queen Alexandra Sanatorium in Davos. This institution was founded chiefly as a result of the labours of the late Lord Balfour of Burleigh, to secure the advantages of sanatorium treatment in an alpine climate for persons of small means of the English-speaking nationalities suffering from curable tuberculosis but unable to afford the ordinary expenses of such treatment. A daily average of 40.7 patients were in residence during 1914, and at the general meeting held in July of that year the eminently satisfactory eleventh annual report was presented. It was decided to complete the last few unfinished items of the building, and orders were given to that effect.

* Cf. Sir Clifford Allbutt, "The Training of the Medical Student," BRITISH MEDICAL JOURNAL, September 2nd, 1922 ("University v. Technical," p. 468).

A few days later the blow fell; the male servants were called up for military service, and all except three of the female staff left in a panic. Most of the patients returned home as soon as travel was possible, and the remainder were transferred on the approach of winter to a hotel in Davos. In April, 1915, the work of the sanatorium ceased entirely. The building thus remained empty until 1922, an offer of its use for convalescent or sick soldiers being declined by the War Office. During these years the overhead charges continued to run, and when the time came for reopening there was no balance available for the large initial outlay, and an appeal for this purpose proved fruitless. Last summer the building was sold to the cantons of Thurgau and St. Gallen for a popular sanatorium and the proceeds were invested to serve the original object of the Fund. Legal advice at this stage made it clear that the income must continue to be applied towards the treatment of patients in an alpine climate—that is to say, in Switzerland and not in Great Britain. Sale of the building itself was not held to constitute failure of the original object. Of the possible alternatives the Council decided on a system of money grants conditional upon treatment being taken at some approved place. The gross income available for such grants is expected ultimately to reach £1,800 a year. The establishment approved for the purpose is, for the present, the Hôtel Frei, Davos Platz, where the charge, made to nominees of the Fund for board and lodging will be fr. 12.50 a day. This charge includes a separate room, central heating, and electric light. Rooms will be assigned by the local committee. The visitor's tax of 55 centimes a day will bring the hotel charges up to fr. 13.05 a day, or fr. 91.35—equivalent to about £4—a week. Assistance from the Fund will be given in the following form: (a) a grant of fr. 38 a week towards the hotel bill (paid direct to the hotelier), (b) free medical attendance by a visiting physician, (c) free nursing by a resident nurse, (d) payment for medicines and bacteriological examinations ordered by the physician. The net cost of maintenance and treatment to an assisted patient (excluding personal laundry) is estimated not to exceed £2 10s. a week. Assistance is limited to the winter months and to a period of six months in all. The cost of the journey is borne by the patient; a second-class single ticket from London to Davos Platz costs about £5 15s. Those aided by the Fund will be expected to stay throughout the winter season. The medical report on which assistance is granted is filled in by the applicant's usual medical attendant, for submission to one of the examining physicians to the Fund. Dr. Arnold F. Bill and Dr. Florian Buol are the visiting physicians in Davos. Application forms and further information will be sent by the Secretary, Queen Alexandra Sanatorium Fund, Davos Platz, Switzerland. Copies of the forms only can also be had from the Honorary Secretary to the Council, Mr. D. VCsey, 3, Camp View, Wimbledon Common, London, S.W.19.

NAVAL MEDICAL SERVICE MEMORIAL.

A short time ago (August 26th, 1922, p. 396) we published an account of the unveiling of a memorial tablet at Haslar Hospital to the members of the naval, medical, and nursing services who fell in the great war. A similar memorial tablet, dedicated to the memory of the medical officers, sisters, V.A.D.'s, sick-berth staff, and sick-bay reserves of the Royal Navy who fell in the great war, has now been erected at the Royal Naval Hospital, Plymouth. It was unveiled on October 4th by Surgeon Rear-Admiral Sir Daniel McNabb, principal officer of the hospital. In his dedicatory speech he dwelt especially upon the spirit of comradeship that ran through all ranks of the navy, knitting them together in a bond of devotion to duty and to their country. The medical staff, he said, in action lacked the excitement of the fighting man; their duty was especially to keep themselves as cool and unconcerned as though at a surgical demonstration, and to exercise the same delicate skill that they would display in the operating theatre of a hospital at home. The type of man who could do this was of no ordinary kind, and it reflected the highest credit on the medical service of the

navy that its duties under such trying circumstances should have been so brilliantly and efficiently discharged. Among those present at the ceremony were Surgeon Vice-Admiral Sir Arthur May, Surgeon Rear-Admiral Sir William Pryn, representatives of all ships and establishments, and of the British Red Cross Society and the St. John Ambulance Association.

EXHIBITS AT THE ROYAL COLLEGE OF SURGEONS.

THE excellent practice of displaying specimens recently added to the museum of the Royal College of Surgeons of England in one of the rooms is being continued this year. The specimens are now on view in Room 1, and will so remain until November 10th. Some eighteen months ago a number of subscribers presented to the College the collection of anatomical specimens of the anatomy and lesions of the nose formed by the late Professor Onodi. Nearly one hundred of these have already been redissected and remounted and are included in the collection now shown. Amongst the other exhibits at Lincoln's Inn Fields are a series of specimens demonstrating the circulation in the shark which have been made by Mr. R. H. Burne, the physiological curator to the museum, as well as a number of pathological specimens of interest, presented by different surgeons and physicians.

THE MEDICAL SOCIETY OF LONDON.

THE one hundred and fiftieth session of the Medical Society of London opens on Monday evening next, October 16th. The annual general meeting will be held at 8 o'clock, and the President (Mr. James Berry) will vacate the chair in favour of his successor, Lord Dawson of Penn, G.C.V.O. The presidential address will then be given by Lord Dawson on "Certain developments in medicine," to be followed by a discussion. An interesting programme has been drawn up for the first half of the ensuing session. On October 30th a clinical meeting will be held for the exhibition of cases and radiograms illustrating tumours of the abdomen (other than those of the female appendages). On November 13th there will be a debate on "pernicious anaemia," and on November 27th a discussion on blood transfusion in civil practice. On December 11th Sir William Willeox will introduce a discussion of the clinical, pathological, and radiological aspects of infections of the teeth and gums. These meetings will be held at 8.30 p.m. at 11, Chandos Street, Cavendish Square. The Lettsomian lectures will be given in February and March, 1923, by Mr. W. Ernest Miles on carcinoma of the rectum, and Dr. J. Walter Carr will deliver the annual oration in May.

THE PRINCE OF MONACO'S BEQUESTS.

THE late Prince of Monaco bequeathed the sum of 1,000,000 francs to the Académie de Médecine, the income to be used for a prize every second year. He bequeathed the same sum for a similar purpose to the Académie des Sciences, the nature of the subject to be selected in each case by the Academy in relation to the needs of the moment. He bequeathed to the Institute of Human Palaeontology, founded by him in Paris, all his books, drawings, and specimens relating to the subject, and directed that a scheme should be drawn up for research work and investigation to establish scientifically the history of man and his origins. He also left 700,000 francs to Dr. Jules Richard for the completion of scientific and literary work in connexion with the great Oceanographic Institute at Monaco, which has a branch in Paris, and other moneys, together with his books and collections, to the same Institute. To the French Academy of Agriculture he left his farm at Ste-Suzanne, to be maintained as a place for agricultural experiments, and as evidence of what science and determination can obtain from unpromising soil.

THE first social evening of the new session of the Royal Society of Medicine will be held on Wednesday, November 8th. The new President, Sir William Hale-White, and

Lady Hale-White will receive the guests at 8.30 p.m., and at 9 p.m. Sir John Bland-Sutton will give an address entitled "Spolia Memorabilia; Shrunk Human Heads, Labrets, and Ear-plugs." Music and light refreshments will be provided.

THE BACTERIOLOGY OF TINNED MEAT AND FISH.

The Food Investigation Board of the Department of Scientific and Industrial Research has issued this week a timely report by Dr. W. G. Savage, Mr. R. F. Hunwicke, and Mr. R. B. Calder, on the bacteriology of canned meat and fish.¹ It consists of five parts. The introductory section deals with methods of examination and record, cultural tests and bacterial classification, and gives a summary of the foods examined; Section II describes the organisms isolated and discusses their significance; Section III records a special investigation into the relationship between oxygen requirements and decomposition changes in tinned foods; Section IV discusses generally the results obtained from these researches; and the concluding section reviews briefly the work of other investigators. The pamphlet ends with a useful list of references to the literature of the subject.

Aim and Method of the Inquiry.

In approaching this investigation the following considerations and lines of inquiry appeared to the authors to be of primary though not of equal value:

"(a) To study how far canned foods contain living bacteria or their toxic products, which are capable, under favourable conditions, of setting up food poisoning or food infections. This applies not only to canned foods which are rejected by the tests employed by inspectors, but also to food passed and consumed as being sound.

"(b) To ascertain to what extent canned foods passed for consumption are free from bacteria, and, if not sterile, the importance and significance of the bacteria found.

"(c) To study the bacteria associated with and concerned in the spoilage of canned foods with a view to diminishing wastage from such causes."

The total amount of canned foodstuffs lost through spoilage is enormous, though it is now relatively small in proportion to the quantity canned. To diminish this wastage to the lowest possible figure can only be achieved if the bacteria which cause spoilage are known, their modes of introduction ascertained, the conditions necessary for their growth elucidated, and the efficiency of the sterilization processes studied in the light of the actual bacteria found both before and after sterilization. While an exact study of the bacteria present is essential, other considerations come in, and the authors made it their aim to investigate the subject as a whole in all its bearings. This led them to make a number of subsidiary researches—for example, into the chemical properties of the organisms isolated under the conditions occurring in canned foods, and into the relative suitability of the different foods as culture media.

The present report is confined to meat and fish, which present very similar problems; fruit, vegetables, and milk will be dealt with in later reports. For the purpose of this investigation 344 samples of tinned meat and tinned fish (including crustacea) of different kinds and from various sources were examined. Some were ordinary samples passed by the inspectors or purchased in shops, but most of them had been rejected for one reason or another. Nearly all the meat tins contained corned beef, and no samples of made-up meat products were included. Each sample was very thoroughly examined, and the findings were compared with the physical characteristics of the unopened tin, with the characters of the contents after opening, with direct microscopic examination of the food, and with the chemical findings. Besides this many sound tins were experimentally inoculated with pure cultures of the bacilli isolated. Full details are given of the methods of examination and recording adopted, and the precautions taken to avoid outside contamination. In every case the cultural characters of the organisms were studied in pure culture. Certain characters were recorded as of special importance—namely, powers

of resistance, conditions as regards oxygen requirements, optimum temperature for growth, and ability to decompose proteins. Here it may be noted that the indol test was found of no value in distinguishing between types of bacteria which can decompose tinned foods and those which cannot.

The Organisms Isolated.

The micro-organisms isolated were classified into six groups: (1) moulds and yeasts; (2) obligate anaerobic bacilli; (3) sporing aerobic bacilli (excluding thermophiles); (4) thermophilic bacteria; (5) non-sporing aerobic bacilli; (6) micrococci.

(1) Yeasts, though plentiful in tinned milk and fruit, are scarcely ever found in tinned fish or meat. The presence of moulds is evidence of air access; there is nothing to show that it can cause either "blowing" of tins or extensive decomposition of the meat, but it makes the food unpalatable.

(2) Anaerobic bacilli were looked for in every sample, for the important part these were likely to play was recognized. They were found in 27 samples—9 meat tins and 18 fish tins. Seven strains corresponded with *B. sporogenes* and 12 with *B. rauschbrandii* type. The former type of organism was found capable in pure culture of producing putrefactive decomposition in canned meat with obtrusive "blowing" of the tin; the latter caused gas development and, if given time, it led to pronounced decomposition. It appears that obligate anaerobes, if they get a chance to grow, always produce profound changes in the food.

(3) Assuming that sound canned foods are not of necessity sterile, it is important to distinguish between the types of organism which may be looked upon as actual or potential causes of decomposition and those which are harmless concomitant bacilli. From this point of view the ordinary sporing aerobic bacilli are of much consequence because of their wide distribution in canned foods, their great resistance to heat, and the ability of most of them to break down proteins. Special attention was therefore paid to this group as a cause of unsoundness in tinned food. Since there is at present no satisfactory classification, the authors made no attempt to give names to most of the strains, but classed them into alphabetical subgroups. In regard to the significance of this group, the two main questions were whether its members possessed any pathological or harmful significance, and whether they could decompose meat or fish either under ordinary conditions or in specially favourable circumstances. Most of them were found to be widespread saprophytic bacteria devoid of any pathogenic properties. Studying the relation between decomposition and sporing aerobic bacilli, the authors found that their presence, as such, even if proteolytic, cannot be accepted as evidence of unsoundness. Nevertheless, it is conceivable that in special circumstances they may have been the cause of the unsound condition of the tins with which they were associated. For instance, the presence of small leaks, by permitting access of air, might possibly supply the oxygen necessary for their growth and enable them to multiply and decompose the food.

The factor of access of air assumed greater importance as the inquiry went on; but from time to time the authors came across strains of aerobes which grow well under anaerobic conditions, and careful investigations were made.

"It is evident from these experiments that sporing aerobes are very widely present in canned meat and marine products even when the tins are sound and the contents perfectly good. Although most of them are capable of readily decomposing proteins under favourable conditions of growth and temperature, they do not do

so in many tins, because the supply of oxygen is small—possibly a majority—possess the strict anaerobic conditions, but at the same time less than would occur if oxygen were present. These conditions they do not cause decomposition of the inadequate growth, or because a supply of oxygen is necessary for the manufacture of proteolytic enzymes. Such a conception at once emphasizes the importance of leaks in the tins. Given a hole in the tin which will admit sufficient air, our experimental results show unmistakably that these strains will not remain dormant but will multiply, produce proteolytic enzymes, and decompose the contents. In most of our experiments the air access holes were about 4 mm. in diameter, but . . . the same result may be obtained with pin-hole leaks."

(4) Thermophilic bacteria are widely distributed in canned foods, even when the contents are perfectly good in every way. Their wide distribution in sound products and their negative properties (inability to produce gas or decompose proteins) indicate that they are not a cause of spoilage of this kind of canned food, either in natural conditions or as a potential cause when small leaks allow the entry of enough air to enable them to multiply.

¹ *The Bacteriology of Canned Meat and Fish*. By William G. Savage, M.D., B.Sc., R. F. Hunwicke, B.Sc., A.I.C. and R. B. Calder, B.Sc. Special Report No. 11. London: H.M. Stationery Office. 1922. (Pp. 72, 2s. 6d., post free.)

(5) For the purpose of this inquiry the important features of the non-sporing aerobic bacilli are the possession of proteolytic properties and the ability to ferment carbohydrates with the production of gas. In all 78 organisms were isolated and classified amongst the divisions of this group. Those with both liquefy blood serum and ferment carbohydrates with gas production are an important cause of decomposition in canned meat or fish. Those which ferment carbohydrates with gas formation may "blow" the tins but do not lead to much decomposition. Those which are neither proteolytic nor fermentative have no significance as causes of unsoundness.

(6) Micrococci of different kinds were present in some 23 per cent. of the samples. Most of them were morphologically diplococci; but staphylococci, streptococci, and here and there a sarcina, were also isolated. The authors are confident that micrococci play no part in causing unsoundness, and the reasons for this opinion are stated at length. These strains cannot by themselves in the ordinary way cause decomposition in canned meat or fish; nor were any facts observed suggesting that they may act symbiotically and so assist more active strains. In the absence of any leak they can sometimes survive the sterilization processes.

Throughout this investigation no bacteria of the food-poisoning types were detected, and there was nothing to suggest that the organisms associated with the unsound conditions present were pathogenic to man.

Soundness and Sterility.

A full account is given of a special inquiry into the relation between oxygen requirements and decomposition, leading to the opinion that minute leaks act not so much as sources of infection, but as sources of oxygen which light up and set into activity the dormant germs which are there already.

In their general discussion of the results the authors deal first with the comparative sterility of sound samples. Of 76 shop samples, whose contents were perfectly sound, 47 were not sterile, but this was almost wholly due to sporing aerobic bacilli, thermophilic bacilli, and micrococci. These, it seems, are to be looked upon as the survivors of bacteria originally present; they are not invaders through leaks in the tins. Such surviving bacilli do not in any way injure the foods they inhabit because they cannot multiply and decompose under the existing conditions.

"The importance of our findings is not that they indicate any danger to health but that (a) they show that sterility is not in itself a reliable test of soundness and that samples cannot be justifiably condemned merely because they are not sterile; (b) they emphasize the fact that unsoundness in tins is not solely or even usually due to outside contamination but that tins may become decomposed and unmarketable not because outside bacteria gain access but because the conditions within the tin have become changed (for example, by access of sterile air) in such a way as to enable bacteria already present to multiply and decompose the food."

The chief practical conclusion to be drawn from this report is that the conditions under which tinned meat and fish go bad are far more complex than is generally supposed.

"The prevailing view is that canned food tins become unsound according as to whether they do or do not contain bacilli of the decomposing type. Indeed, the ordinary view is still simpler. It is supposed that if the processes of preparation are satisfactory the food contained in the tins is sterile and remains sound, but that if the sterilization is inadequate or leaks subsequently develop bacteria are left alive or gain access, and the food becomes unsound. The type of bacterium present is hardly considered. These simple conceptions cannot be maintained. We have to regard canned meat and fish products as at the best only partly sterilized, and for the most part as containing viable bacilli, many of which are of a decomposing type. The food is sound rather on account of its being free of oxygen than because it is sterile."

Whether the food becomes unsound depends upon many factors, of which the following all play a part: (a) the extent and type of the bacterial contamination; (b) the efficiency of the "processing" (sterilization by heat); (c) the access of air to the tins; and (d) the temperature environment of the samples.

The Moral for the Manufacturer.

The moral therefore is that the manufacturer who wishes to ensure the absence, or at least a minimum, of spoilage in tinned meat and fish must be encouraged to do five things: he should obtain his food products as fresh as practicable; he should tin them as speedily as possible under conditions of great cleanliness; he should treat his products so as to ensure the presence of a vacuum; he should employ the right "processing" temperatures; and lastly, by the use of good quality tinplate and efficient tin-closing methods he should avoid causes of leakage, and so maintain the vacuum.

England and Wales.

JUBILEE OF MANCHESTER SCHOOL OF MEDICINE.

The jubilee of the Manchester School of Medicine was celebrated on October 4th, when the Dean of the Medical Faculty, Professor R. B. Wild, received a large number of guests, who were shown over the medical school and the recent extensions of its laboratories. Sir Humphry Rolleston, President of the Royal College of Physicians of London, delivered a lecture on the subject of "Recent physiology of the liver in its application to practice." Sir William Milligan, who presided, paid an eloquent tribute to the work which Sir Humphry Rolleston had contributed to the science and art of medicine. Professor G. R. Murray, who also spoke, said that it was not generally remembered that Sir Humphry Rolleston, while at Cambridge, had represented the university on the football field.

The medical school at Manchester was founded by Thomas Turner in 1824, in connexion with the Manchester Royal Infirmary. Previous to this London had enjoyed a monopoly of medical education in England, and Turner's medical school in Manchester was the first to be recognized outside London. William IV conferred the prefix of "Royal" upon it. The Manchester Royal School of Medicine was amalgamated with Owens College in 1872, and Turner died in the following year having been able to deliver the opening address of the amalgamated college nearly fifty years after his foundation of the medical school. In 1880 Owens College became the first college of the new Victoria University for the north of England, and three years later the new university became empowered to confer its own medical degrees. Enlargement in 1883 and 1894 brought the medical school to its present size, and a further great advance was made when the Royal Infirmary was rebuilt on its present site in 1908. A rearrangement of the interior of the medical school last year has almost doubled the laboratory accommodation for teaching and research.

UNIVERSITY COLLEGE HOSPITAL DINNER.

The First Administrations of Ether.

The annual dinner of past and present students of University College Hospital was held at the Hotel Cecil on October 6th, with Sir Dawson Williams in the chair. The company numbered 110, and included Sir Rickman Godlee, Sir John Rose Bradford, Sir Frederick Mott, Mr. Raymond Johnson, Sir J. H. Parsons, and Major-General Sir A. P. Blenkinsop.

After the King's health had been honoured, the Chairman proposed prosperity to University College Hospital and Medical School, and recalled that it was the first hospital in this country to be built as a teaching hospital. Speaking of the history of the buildings in Gower Street, he said that the spirit of the old dingy hospital of former days, overmastered the inferior accommodation, and admirable work was done then under most unfavourable conditions. The chairman had before him on the dinner table a chairman's bell presented to University College Hospital by Dr. F. W. Cock. It is one of two bells both cast from the same ingot as the two new bells recently hung in Westminster Abbey. Each was suspended from an iron support made from the railings of the old operating theatre in University College Hospital. The other bell Dr. Cock presented to the Massachusetts General Hospital. Both bells were engraved with the names of the "General Hospital, Massachusetts," and "University College Hospital," with the dates, and both bore also the monkish Latin rhyme of the eighteenth century often found on church bells, "Nola pulsatio amoris ratio," which may be freely translated "When I do sound let joy abound." The chief bell found in early times, it should be explained, was at Nola in Campania, so that the name of the place became synonymous with bell. The gifts were intended to commemorate the fact that ether was first administered as a general anaesthetic in the Massachusetts General Hospital on October 16th, 1846, and was first so administered in Europe at University College Hospital on December 21st of the same year. The operation at Boston was for a vascular tumour of the neck and was performed by Dr. Warren. The operation at University College Hospital was for amputation above the knee and was performed by Mr. Liston. The chairman read a letter which Dr. Cock had received from the board of trustees of the Massachusetts General Hospital in which they expressed their gratification of all the bell presented to them. "They value it," the letter continued, "most highly not only for these reasons but also as a generous expression of that friend

A large number of non-tuberculous cases have also been examined, consisting chiefly of suspects. The decrease has occurred in both the pulmonary and non-pulmonary forms of tuberculosis. The total number of patients treated during the year was 6,571, and the total deaths from all forms of tuberculosis in the city was 855, giving a ratio of 1 to 7.6 of those coming under the scheme. As regards the influence of occupation, there are the usual large numbers of servants, doffers, spinners, stitellers, and also many labourers and housewives. Of the patients 418, or 41 per cent., were found to be living with other tuberculous patients, but the number sleeping in the same room has steadily decreased each succeeding year. Dr. Trimble again emphasizes the necessity for increased cleanliness to limit infection. The usual distribution of the disease is observed: the crowded, poorer districts are most heavily affected; the residential, "garden-city" districts are least affected. The tuberculosis nurses paid 49,270 visits, and Dr. Trimble insists on the great value of their work, both for prevention and treatment. In an interesting and important section dealing with pregnancy and tuberculosis is a table giving a brief analysis of the result of pregnancy in 1,120 tuberculous women; 8.3 per cent. miscarried; 89 per cent. were delivered of a living child at full term; 2.7 per cent. were delivered of deadborn children at full term; among the 8.3 per cent. other causes may have been at work. Dr. Trimble arrives at the conclusion that tuberculosis is not a very active cause of premature birth. In another table he gives the result of pregnancy on the clinical course of tuberculosis in 992 cases: 28.6 per cent. were improved; 49.7 remained unchanged; 16.2 were worse; and 5.5 per cent. died within one year of delivery. These figures are new and important, and show that the question of prognosis must be reconsidered. The x-ray, dental, and bacteriological departments all show increasing figures, as is to be expected with their over-growing importance. An interesting account is given of the open-air school and of the municipal hospital for the osseous forms of tuberculosis. The school started in March, 1921, with 20 pupils; on March 31st, 1922, the attendance roll was 105. A large open garage at Graymount has been converted into an open-air day school; it can be protected from wind and rain coming from any direction; on the original concrete floor there has been laid down a circulating hot-water system, over which is laid a sectional wooden floor, so that even on the coldest and wettest days the children's feet are kept warm; Dr. Trimble testifies to the great physical improvement of the children at the school. In the hospital there are only 47 beds, but over 200 are required, and a seaside convalescent branch is also very necessary. The last pages of the report are devoted to charts and sections showing the steady fall in incidence and in mortality of tuberculosis in the last forty years.

Correspondence.

SERUM BY THE MOUTH.

SIR.—In the JOURNAL of July 1st (p. 29) Dr. Allison gives his experience of the use of serums and vaccines by the mouth. He began to use serums orally in 1892. In *New Serum Therapy* (Baillière, Tindall, and Cox, 1906) I mentioned several who had reported the use of antidiphtherial serum orally for diphtheria and hypodermically for sepsis as well. Dr. Allison evidently was early amongst all such explorers, and it was from where they were and where Dr. Allison admits he still is that my work began.

In *New Serum Therapy* the action of serums by the mouth was defined as being neither antitoxic nor antibacterial so far as its specific action on the organism was concerned. The other elements in the serum were described as elements controlling tissue tone and probably of glandular origin. A sharp line of division was made between normal serums and those which were the product of acquired immunity. In *Hormone Therapy by Sera, Vaccines, and Drugs* these other elements were recognized as hormones, and that they were the basis not only of tissue metabolism but also of tissue immunity. Their action was not obtainable by hypodermic injection of the serum any more than the specific effects of the antitoxic and antibacterial elements were obtainable by oral exhibition. It was also stated that to obtain the full immunity possessed by the animal supplying the serum it had to be given both orally and hypodermically—orally for

the hormone action on the tissues, and hypodermically for its specific action on the toxin or organism.

In both publications the hormone action on the tissues was recognized as non-specific and extended to any antigen to which the tissues were toxophil. Dr. Allison's experiment with cooked thyroids is extremely interesting, and confirms my contention that the active principles of the endocrine glands are not affected by being administered orally in their natural medium any more than when they are the crude product of the laboratory.

May I correct the slip pointed out by the reviewer?—"Antidiphtheria serum from a culture grown on a solution of normal serum." In such a subject it is difficult to confine oneself to a reasonable space, but in the work published theory and practice are fully detailed.—I am, etc.,

Melbourne, Aug. 23rd.

D. MONTGOMERIE PATON.

CHLALMOOGRA OIL IN TUBERCULOSIS.

SIR.—Major Garrothers will find the information he asks for in his letter in your issue of October 7th (p. 656) in the following papers by me on trials made during the last three years in tuberculosis of the soluble preparations of chlalmooгра and other oils, which I have used successfully in leprosy: (1) Sodium morrhuate in the treatment of tuberculosis, *BRITISH MEDICAL JOURNAL*, February 8th, 1919; (2) The successful treatment of leprosy by injections of soluble preparations of the fatty acids of chlalmooгра and other oils, and its bearing on the tuberculosis problem, *Practitioner*, August, 1921, p. 77; and (3) The application of tuberculosis of the successful treatment of leprosy by soluble preparations of chlalmooгра, cod-liver, and other oils, *British Journal of Tuberculosis*, 1922.

I shall be glad to give any further information desired to those willing to test the treatment under the carefully controlled conditions which are essential to our present state of knowledge, as it is possible to do harm in pulmonary tuberculosis, at any rate, with these powerful preparation although trials now being carried out in several institutions in careful hands are not without some signs of promise. I am, etc.,

LEONARD ROGERS.

London School of Tropical Medicine, Oct. 9th.

CARDIOLOGY.

SIR.—I shall esteem it a great favour if you will allow me to comment upon your review of my book in the JOURNAL of September 30th (p. 601), for I am extremely anxious that should be no misunderstanding as to the views I have put forward upon the important point raised by your review. These are his words:

"His detailed and reasoned criticism of the interpretations records from the jugular vein is vitiated by the fact that he did not recognize that these tracings are records not of pressure but of volume."

I am somewhat at a loss to know what precisely meant by this statement, that the jugular tracings are volume records, but as we are dealing with dynamics (fluids motion) I presume that he means changes in the volume of the blood in the jugular vein obtaining during the cardiac cycle. If I am right I would ask in turn, What is it that determines these changes in volume, if not changes in pressure?

The determining cause of the systemic circulation as a whole is the pressure developed within the left ventricle during its systole. This pressure is transformed into head of pressure within the aortic sac, upon which depends the circulation through the arteries, capillaries, and veins. During this course the pressure is continuously falling in exact proportion to the resistances overcome by the moving blood. As we near the terminal venous trunks the force of the ventricular systole is nearly spent, and accordingly find very low pressure readings in the veins at the root of neck, even to minus quantities. At this point the evenness of flow previously maintained in the veins is broken. It shows haltings and accelerations, attended by congestions, depletions, the vessel wall rising and falling as the one or other condition occurs. The filling up of the vein is by aff from behind, and it points to an impediment in front; subsidence of the vein indicates withdrawal of the impediment.

What is it that holds up the venous inflow and then releases it? What but changes of pressure within the auric ventricular chambers?—for the *vis a tergo* driving the venous blood will only yield to a *vis a fronte* on the heart side.

At times the filling of the jugular vein is not merely due to influx from behind; there may be actual reflux from the heart into the veins at two points in the cardiac cycle—namely, (1) the auricular systole, (2) the ventricular systole (especially when the tricuspid valve is incompetent). Intravenous pressure will, of course, rise and fall with each venous distension and subsidence.

There remains yet another cause productive of movements in the internal jugular vein, this time independently of any alteration of volume of blood in the vein. Such is the impact upon the vein of any force from without, and this is illustrated by the carotid artery where it abuts upon the vein, the artery transmitting to the vein its share of the percussion wave projected by the left ventricle at each systole.—I am, etc.,

London, W., Oct. 6th.

HARRINGTON SAINSBURY.

PSYCHO-ANALYSIS.

SIR,—If I mistake not, the correspondence upon this subject which has been proceeding in your columns arose primarily in connexion with the attitude which should be assumed towards it by the family doctor. The latter will find a very useful guide in the admirable, scholarly, and scientific address delivered last week (see October 7th, p. 655) by one of our most respected, cultured, and revered physicians—Sir Clifford Allbutt. Some time ago you were good enough to print a letter from me calling attention to the psycho-analysts' views as to dreams. It elicited one or two rather unimportant comments which did not seem to give further information in the desired direction. It was, for instance, suggested that "desultory reading" was not sufficient to warrant comprehension or criticism. Without being intentionally ogotistical, I may mention that since retiring from practice I have had more leisure to peruse such works as interest me on the various branches of medicine than falls to the lot of the average general practitioner. Without being accused of conceit, I may, perhaps, be permitted to lay claim to average intelligence. It would thus be fair to assume that what is unintelligible to me will also be unintelligible to him. If this be so, it is only reasonable that he should be suspicious of a method which cannot be demonstrated and which does not seem to rest upon a basis of biology.

Psycho-analysts seem to rely largely upon unproved metaphysical assumptions, and it may be that for this reason their propositions have been too readily accepted at their own valuation. Thus it is possible that the more credulous medical men tend to assume that reasoning which rests upon a branch of knowledge with which they are not conversant is sound, while on the other hand scientific psychologists may be misled by believing that the support of physiologists and of these may be induced to state Sir Clifford Allbutt has brought the subject before us in such a definite manner.

In any case it is difficult to see how psycho-analysts can refrain from putting forward a reasoned defence of their position without giving that position entirely away. I do not know whether they have ever published any statistics to prove that those who regularly attend confessionals are less liable to those neuroses which they attribute to repression. Should they have done so or be able to do so it might go some way towards supporting their position.—I am, etc.,

Harrogate, Oct. 8th.

P. McBRIDE.

UNSUSPECTED PREGNANCY.

SIR,—In view of Dr. Graham Grant's sweeping assertion that no "woman of average size with uterine contents of average bulk" can go to full time without suspecting her condition I beg to record the following case.

On October 25th last year I was called to see a patient on account of a "swelling in the stomach," which was suspected to be a tumour. I found the patient to be a primipara, aged 33, of normal stature, but rather on the small side. She had been married two years, and was living a happy normal married life with her husband. I found her on examination to be nine months pregnant, and when I informed her of her condition she received the news with incredulity, and it was not until two days later when she was delivered of a healthy 7 lb. child that she would accept my diagnosis as correct.

It is interesting to see how the signs of pregnancy were satisfactorily accounted for without arousing suspicions as to her condition in the mind of the patient or her husband. This is even more remarkable when one takes into consideration the fact that she is a woman of normal mentality, who left school on reaching standard five, which I am led to believe indicates an average degree of intelligence.

1. The cessation of menstruation was easily explained to her own satisfaction, as she had always been irregular, but she believed to anaemia.

2. The vomiting of pregnancy was slight, and was similarly easily accounted for as she was of a "bilious nature," and subject to vomiting and feelings of nausea on the least provocation.

3. Fœtal movement was felt, but passed unrecognized, the symptoms being attributed to "wind" for the treatment of which she resorted to aperients. When these failed to stop the "rumblings" the husband cleverly dealt with the situation by administering brandy, which the patient assured me never failed to give immediate temporary relief.

4. A great improvement in appetite was held responsible for the increase in girth and general dimensions, until a few days before labour, when a tumour was suspected. I am indebted to this last most alarming suspicion for my professional attendance on what has proved to be a most interesting case. The husband noticed the increasing proportions of the abdomen and breasts, but never gave pregnancy a thought. However, to explain it he went one step further in the misdiagnosis, and attributed the increase of appetite of his wife to the invigorating air of the district, to which they had recently come to live.

The patient had no reason to hide her pregnancy; in fact, both she and her husband were delighted at the discovery, though somewhat nonplussed by the difficulty of providing baby necessities and a nurse at so short a notice.

Strange as all this may read, I would remind the "doubting Thomases" that sometimes, and especially in this particular case, facts are more strange than fiction.—I am, etc.,

R. W. HOBSON-JONES, M.R.C.S., L.R.C.P.

Caterham-on-Hill, Surrey, Oct. 8th.

SIR,—The case I reported (September 23rd, p. 578) happened in the last years of the war. The patient's husband was in France, and she lived with her mother, who washed her linen for her, and by so doing was able to note the regularity of her daughter's periods. The patient was a fine, well-modelled woman of average height, such as one might infer of anyone engaged in her employment. The baby and placenta were of average size. There was no reason to question the *bona fides* of the patient, her mother, or the representative of the firm for whom she was working. If the patient was lying to me and had been conscious of her condition it is all the more surprising that she should engage herself as a mannequin.

In view of the facts of the case as observed by or reported to me it would be more judicious if Dr. Graham Grant did hesitate before asserting that a woman cannot go to full time without suspecting her condition.—I am, etc.,

Manchester, Oct. 9th.

ALFRED WILLIAMS, M.D.

SIR,—Will you kindly allow me a little space to answer Dr. Graham Grant (p. 651), especially as the question of unsuspected pregnancy came up in a recent *cause célèbre*. The answer to (a) has been fully given; (b) the woman was slim. The answer to (c) was given also.

The woman was living with her husband, who summoned me.—I am, etc.,

London, S.W., Oct. 6th.

J. FLETCHER.

THE THYROID GLAND AND DISEASED TONSILS.

SIR,—In reply to the letter of "M.A., M.D." (October 7th, p. 662), I regret the ambiguity to which he has drawn attention. What I meant to say was that the removal of a focus of septic absorption such as diseased tonsils must be thought of in relation to possible structural damage already inflicted upon the endocrine system, and, as such, irremediable. I did not intend to suggest that the removal of tonsils *quâ* tonsils had any known relation to endocrine function.—I am, etc.,

London, W.1, Oct. 7th.

H. CRICHTON MILLER.

Obituary.

ARMAND BERNARD, B.A., M.B.DUBL., L.R.C.S. EDIN., Consulting Surgeon, the Lock Department, Royal Infirmary, Liverpool.

The death of Dr. Armand Bernard has come as a surprise to many of his friends in Liverpool. At the end of the war Dr. Bernard retired from active practice in the specialty with which he had so long been identified. He however continued in his work as a member of the Birmingham War Pensions Committee. Towards the end of last year his health began to fail, and after a lingering illness he passed away at Millom in Cumberland, on October 4th, at the house of his son-in-law, Dr. John Pratt, D.S.C.

Dr. Bernard studied medicine at the University of Dublin, and graduated B.A., M.B. in 1870. In the following year he

We regret to record the death of Dr. T. D. LUKE of Clevedon, Somerset, which took place on September 25th after an acute and brief illness. Thomas Davey Luke was born in 1873 at Scorrier in Cornwall, and went from Truro School to Queen's College, Belfast, graduating M.B. of the Royal University of Ireland in 1894 and M.D. in 1908. He obtained the Fellowship of the Royal College of Surgeons of Edinburgh in 1902. While a student at Belfast he won a scholarship in medicine at Queen's College, and the Malcolm and Coulter exhibitions at the Royal Victoria Hospital. For several years he enjoyed an extensive practice in anaesthetics in Edinburgh, and was lecturer in that subject at the University of Edinburgh and the first anaesthetist to the Edinburgh Royal Infirmary. But his health, which was never of the best, compelled him to relinquish these posts, and he became medical superintendent of the Peebles Hydro, for which previous experience at Matlock and Grango-over-Sands had fitted him. Dr. Luke wrote two small works on practical anaesthetics, which each passed through several editions, and he was known also for his writings on hydrotherapy and kindred subjects. During the war he served as surgeon lieutenant-commander in the R.N.V.R. Two years ago (writes a colleague) pursuit of health again led him to the sunnier south, and he took up practice in Clevedon, where he won immediate and general respect by his genial and kindly disposition, his readiness to promote the welfare of the town, and his untiring work of self-sacrifice. He had an extensive knowledge of therapeutics, and had contributed to some of the leading works on treatment, his latest book on physiotherapy being published this year. Dr. Luke leaves a widow and three young children, to whom deep sympathy is extended in their tragic loss.

Universities and Colleges.

UNIVERSITY OF GLASGOW.

THE following candidates have been approved at the examination indicated:

Finn, M.R., Ch.B.—A. W. Aird, Margaret Alexander, R. G. M.
Alexander, Isabel P. Allan, A. Andersson, A. Ando son, W. C.
Andrew, Margaret B. Balloch..
Sannulla Blair, Mary MacQ.
Dickeson, A. Boyd, P. A. Brown
Janet R. Campbell, Margaret
Norah T. Cassidy, Gladys M.
E. Colville, Elizabeth S. Cro
Gerhardus C. Cruikshagen, J.
C. J. Davidson, Margaret Ma
Isabelle A. Deane, Agnes F. Dickson, Lillian M. Dickson, J. S.
ing, Elizabeth H. Forrest, A.
Tebb,
J. A.
Grant, W. N. Gray, H. G. Halliday, J.
Catherine Harrower, A. T. Hustie, James ..
I. A. Iton
Toad,
W. W. Howie, G. J. Hutchison, Elizabeth G. Jamieson, Jessie M. C.
Jamieson, C. Mark, Jeffrey, T. J. Jones, F. C. Laing, J. E. S. Lee,
A. Leitch, J. Lindsay, G. W. Lochabair, Isabella Lundsen, W. W.
Lundin, H. M. Cluskey, Joan A. P. MacColl, J. W. McConville, Mary
P. MacCunn, A. A. Macdonald, Chissieella Macdonald, T. J.
McNeil, K. W. Mackenzie, Marion A. McKenzie, G. MacKerracher, M.
McLean, N. A. MacLean, S. M. Mahon, R. C. MacMurray, A. M'Kilty,
Marion L. M'Quaker, Mary M. Quaker, Doris M. Walter, Agnes I. Mac,
D. C. Marshall, D. V. Marshall, H. R. Melville, Elizabeth W. Miller,
J. H. Milner, A. Mitchell, T. W. Mitchell, W. Morrison, D. R. Mac
Morrison, Ellen D. Morton, W. Muir, G. J. Muller, J. P. Neilson,
Fannie H. Nelson, Elizabeth K. Nicholson, J. Nicholson, T. Nicol,
J. L. Orr, J. A. R. Oswald, M. G. Pezaro, Louise B. Pollock, T. C.
Potter, Mary L. Proudlove, T. D. Pyke, J. H. Ramage, J. S. Ramage,

Elizabeth C. Rodger, Bessie S. Ross, Mrs. Sarah Ross, J. Russell
Bertha E. A. Sharpe, W. Simpson, Christina H. I. Sloan, A.

Weir, A. F. " " " " " " " " " "
J. H. Wright " " " " " " " " " "

ROYAL FACULTY OF PHYSICIANS AND SURGEONS,
GLASGOW.

The following have been admitted to the Fellowship (after examination): J. A. G. Burton, J. Reid.

Medical Delus.

A NEW winter course of scientific demonstrations arranged by the North of England Branch of the British Medical Association will begin on Thursday, October 19th, at 2.30 p.m. at the Durham County Hospital, when Mr. Hamilton Drummond will deal with treatment of diseases of the colon, Dr. E. Farquhar Murray with border-line gynaecology and Dr. F. J. Nattrass with meningitis. Tea will be served at 4 o'clock, after which an hour will be devoted to the demonstration of cases by the honorary staff of the Durham County Hospital. The second meeting takes place at the Royal Victoria Infirmary, Newcastle-upon-Tyne, on November 16th.

THE opening lecture of the winter session of the Central London Throat, Nose and Ear Hospital, Gray's Inn Road will be given by Mr. Chichele Nourse, F.R.C.S.E., at 4 p.m. on Thursday, October 26th. The subject is "Foundations of Otolaryngology: the work of Flourens."

Mr. PHILIP FRANKLIN will deliver a post-graduate lecture for the Fellowship of Medicine, at 1, Wimpole Street, W., on Tuesday next at 5 p.m., when he will deal with the clinical aspects of tonsils and adenoids. On Wednesday, October 25th Dr. Eric Pritchard will speak at 8.30 p.m. on the feeding of infants from birth to the end of the second year, and on Tuesday, October 31st, Dr. C. E. Lakin will give a lecture at 5 p.m. on indigestion. Other lectures have been arranged for delivery during November and December.

A *COURSE* of nine lectures on maternity, child welfare, and school hygiene will be delivered at the Royal Institute of Public Health, 37, Russell Square, W.C., on Wednesdays, at 4 p.m., commencing on October 18th, when Professor Louis McElroy will speak on the influence of ante-natal care upon infant mortality. No tickets of admission are required.

Dr. R. W. WILSON, having completed forty years in the Poor Law service, has recently resigned. He was appointed medical superintendent of the Croydon Union Infirmary when the institution was opened in 1885. As a mark of appreciation of his thirty-seven years' service in that capacity and also as a medical officer of the union home and children's homes, the Croydon Board of Guardians presented him with a handsome silver rose-bowl and leather album containing an illuminated address and the signatures of the contributors. The staff of the Croydon Union presented him with a magnificent chiming clock inscribed with a record of his services. Dr. Wilson was also the recipient of a china tea-service and a tea-tray from the patients of the infirmary, a breakfast-cruet from the "grannies" of the infirm ward of the union home and a stamp-album from the children in the homes.

The first meeting of the forty-first session of the West London Medico-Chirurgical Society was held at the West London Hospital on October 6th. Sir Leuthal Cheate, retiring president, inducted his successor, Dr. A. G. Wells, who then presented him with the Keckley medal in memory of his year of office. The new President then delivered his opening sessional address, taking as his subject the change which he as a general practitioner had noticed during the last forty-two years.

At a meeting of the University of London Labour Part held at the Essex Hall, Strand, on October 6th, Mr. H. C. Wells was adopted as the prospective candidate of the part at the next general election.

THE Medical Prayer Union will hold a *conversazione* for the reorganization of the Union, at the rooms of the Medical Society of London, 11, Chandos Street, W.1, on Thursday, October 26th, 1922, at 8 p.m., when an address will be given by Dr. Burnett Race, on "The religious implications of psycho-therapy." Intimation of intention to attend would be appreciated by the Honorary Secretary, *pro tem.*, Dr. Tom Jays, Livingstone College, E.10.

THE Wellcome Physiological Research Laboratories formerly at Herne Hill, have been removed to Langley Court, Beckenham, Kent.

THE first dinner meeting of the Hunterian Society will be held at Simpson's Restaurant, Cheapside, on October 16th, at 50 p.m. The dinner will be followed by the presidential address on "The breakdowns of middle life," by Dr. Fortescue; and a paper by Dr. Ernest Young on the treatment of "spepsia in necessitous patients."

AT the September matriculation examination of the University of London there were 67 successful candidates in the first division and 503 in the second division, while 39 gained the supplementary certificate in Latin, three in mathematics, and one in heat, light, and sound.

FOUNDERS' day will be celebrated at the National Hospital for the Paralyzed and Epileptic, Queen Square, W.C., on Wednesday, November 1st, from 3 to 6 p.m. Each visitor is asked to regard this also as a "pound day" and to bring a pound of goods or money for the hospital.

THE National Health Society, of 53, Berners Street, W.1, is arranged for a comprehensive six months' course of training for fully trained nurses and others with certain previous qualifications, who wish to obtain appointments as health visitors and infant welfare workers. The Board of Education has drawn up a definite curriculum for such students, the full course for untrained and younger women being of two years' duration. The fee for a six months' course is 12 guineas, and the new session commenced at the end of September, but students can join later; full particulars can be obtained from the secretary of the Society.

THE Italian Society of Urology will hold a congress at Florence on October 24th, when the principal subject for discussion will be the remote results of prostatectomy, introduced by Professors Gardini and Laslo.

THE Swedish Society of Physicians has decided to bestow an Anders Reizius medal on Sir Charles Sherrington, B.E., M.D., President of the Royal Society, and Waynflete Professor of Physiology in the University of Oxford, for his searches in physiology of the nervous system.

THE nineteenth Italian Congress of Surgery will be held at Florence from October 21st to 25th, when the following subjects will be discussed: (1) duodenal ulcer, introduced by Professor Alessandri; (2) arterial and arterio-venous aneurysms, introduced by Professors De Gaetano and Bolloni.

Letters, Notes, and Answers.

owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

RESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

Persons desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Attilology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.

QUERIES AND ANSWERS.

INCOME TAX.

"E." is buying a practice and the premium is payable partly cash down, partly by instalments.

* (1) No allowance can be claimed for that portion of the total capital sum represented by the instalments, neither can it be deducted therefrom. (2) Interest paid to the bank on an overdraft obtained for the purchase of the practice can be treated as a professional expense.

"O.L.M." is assessed for 1921-22 on the amount of his salary as assistant for that year.

* He was serving in the Canadian forces for 1919. Under an arrangement or concession made by the Board of Inland Revenue any service may be reckoned as "employment" for the purpose of taking an average for the assessment of the earnings of subsequent employment, consequently "J. O.L.M." is chargeable for 1921-22 on his average earnings for the three previous years, or as long as his army service and civilian employment lasted if the period.

"C.G." is an assistant who receives a fixed salary, and whose rent has been paid for him by his employer to the landlord.

* Assuming that "C.G." has the full rights obtainable by payment of the rent he is the statutory occupier, and the amount of rent paid by his employer is assessable on "C.G.," and, of course, properly regarded as an expense of the practice in the same way as the salary.

ASTHMA.

DR. ALEXANDER FRANCIS (London) writes: I think that Dr. Martin (September 23rd, p. 582) would find that a cachet containing caffeine valerian. gr. 2; theobrom. sodiosalicyl. gr. 5, would help his case of polytypic asthma and prevent the necessity of so much adrenaline. One of these cachets can be taken every three or four hours if necessary. Asthma, when associated with nasal polyptosis, is very difficult to deal with, and the removal of the polyptosis usually increases the difficulty. The more complete and perfect the operation from a nasal point of view, the more intractable and desperate is the asthma likely to become. It is not sufficiently well known that asthmatic subjects with a low blood pressure, who have, or have had, nasal polyptosis must not be given aspirin, antipyrin, or oxyquinoline. These remedies in such cases are not only useless, but positively dangerous.

LETTERS, NOTES, ETC.

URINE TESTS.

DR. W. ADAMS CLARK (Penge) writes, in reply to Dr. Washington Isaac's query (September 30th) under this heading: I suggest the use of Benedict's test instead of Fehling's as the best test for routine examination of the urine for sugar. No difficulty occurs with the stopper of the one bottle required. The solution can be obtained ready for use. It keeps well, and is inexpensive. Benedict's test for sugar is made up as follows: Sodium citrate 173 grams, dry sodium carbonate 99 grams, are dissolved in hot water and filtered. In this solution 100 c.c.m. of a copper sulphate solution containing 18 grams of the salt are added, with constant stirring, and the whole blue-coloured solution is made up to 1 litre with distilled water. To carry out the test about 1 inch of the solution is placed in an ordinary-sized test tube, and 8 drops—not more—of the urine added. The mixture is then thoroughly boiled, and the appearance of a spontaneous precipitate which may be green, yellow, or red according to the amount of sugar present in the urine, indicates a positive reaction for sugar. If no sugar is present the solution remains blue, or shows only a faint greenish blue haze. The reagent is not affected by the reducing substances in the urine other than sugar, and the reaction being only slightly alkaline, there is less danger of destroying small amounts of sugar which may be present. The test can be applied in artificial light, since it is the bulk of the precipitate and not so much the colour which gives positive indications of sugar.

PREVENTION OF VENEREAL DISEASE.

"G." writes: The letter by Mr. Herbert Calger on "The radical prevention of venereal disease" in the issue of October 7th (p. 651) certainly raises very vital questions. . . . to what his remedy—"a . . . thinking, practised every day in every way . . . matters) would lead? Could he who loves his neighbour—allow him to work for him at wages incompatible with a decent life? Could shareholders continue to draw interest until the original capital had been refunded many times over, interest which has to be produced by the workers before the rate of wages which the industry can afford to pay is calculated? Can his principle be carried out without changing the whole structure of society?

CORRECTION.

DR. DOUGLAS K. ADAMS calls attention to a clerical error in his paper published last week. In the description 332, col. 1, line 22) the words "right internal rectus,"

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 38, 33, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 36 and 37.
A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 143.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

Angina Pectoris.

A CLINICAL study of 103 cases of angina pectoris was made by S. A. LEVINE (*Journ. Amer. Med. Assoc.*, September 16th, 1922, p. 928), on which were based the following observations: The disease is much more common in males than in females, while vascular hypertension, which plays an important part in the etiology of the disease, is, on the contrary, more common in women. Physical work may account for this discrepancy. The typical patient with angina is a strong, muscular, and well-set person. The disease seems to be comparatively rare in the underdeveloped, poorly nourished, and weak. In this series syphilis was an etiological factor in only six patients. There were seven who had diabetes mellitus, and two who had gout. Organic valvular disease was rarely found associated with angina pectoris. Two patients had typical mitral stenosis, and there were two young patients with rheumatic disease of the aortic valves. The average systolic blood pressure was 160.6 mm., and the diastolic 95 mm. The variations from the mean systolic pressure extended from 80 to 260 mm. About two-thirds were between 140 and 200 mm. Observations on the blood pressure in a few cases were made in relation to the onset of the attack of angina and the administration of nitroglycerin. Two patients showed a marked increase with the onset of the attack, and then a fall as the attack subsided after the nitroglycerin had been given. In a third the change was not significant either as the attack developed or as it subsided under treatment. Examination of the heart in many cases was negative. Of the 103 patients 47 showed no murmurs, 41 had a systolic murmur at the apex or base, and 7 had a diastolic murmur. Of the latter group, 2 had definite and 1 probable syphilitic aortitis, 3 had rheumatic aortic insufficiency, and 1 had mitral and tricuspid stenosis. The heart was generally found hypertrophied on ordinary examination or by orthodiagraphy or electrocardiography. An occasional patient showed no hypertrophy even after the most careful search. The dominant rhythm of the heart in angina pectoris was regular, although there were occasional extra-systoles. Only 1 out of 103 showed persistent auricular fibrillation. The quality and loudness of the heart sounds are of practical importance in angina, especially the first heart sound at the apex. Oedema of the limbs and swelling of the liver are rare, but congestive r  le; at the bases of the lungs are common, especially in those patients with cardiac infarction. The electrocardiograms were occasionally normal in appearance and often showed only slight alterations. There was evidence of left ventricular preponderant hypertrophy in the great majority of cases.

271. **Physiology of the Sympathetic Nervous System.**

L. BARD (*Ann. de M  decine*, June, 1922, p. 453) observes that in the last twenty years so little investigation in regard to the general and pathological physiology of the peripheral receptors and centripetal tracts of the sympathetic system has been carried out that even the existence of centripetal tracts is contested. He refers to the theory of the antagonistic action of the pneumogastric and the sympathetic, and describes the further division of the latter system into two parts—"great sympathetic" and "parasympathetic." The functional antagonism between these divisions is the *leit-motiv* of this theory; the experimental control of their varying reactions to various drugs has become the basic principle of this study. Bard regards the "parasympathetic" as occupying an intermediate position; the "great sympathetic" belongs exclusively to "the life of nutrition," while the parasympathetic appears to be a connecting link with the "life of relation," controlled by the pneumogastric. Gaskell regarded these two divisions of the sympathetic as having different embryonic origins, and Guillaume believes that the connexions between the endocrine glands and the sympathetic system constitute a true morpho-physiological unity. Bard lays down certain theses: "Varying stimuli demand appropriate receptive mechanisms"—hence there is a sympathetic reflex mechanism regulating trophic function, analogous to that of the cerebro-spinal system. "The functions of 'the life of nutrition' fall into three groups, clearly distinct in all details of their biological mechanism." These groups are: (1) muscular apparatus in order to obtain and assimilate all materials necessary to metabolism, (2) secretory apparatus of every kind, and (3) mechanism controlling metabolism. These three groups have a "pendulum-like function—that is, alternation in two phases," each com-

plementary to the other. He illustrates this by reference to accepted physiological phenomena—for example, respiration peristalsis, gland secretion, etc. Bard's next thesis is "Alternation of phases results in oscillations around a position of rest." This double action requires receiving apparatus for the stimuli which are the source of all reflex action. The peripheral receptors of stimuli can only exist in the interiors of organs; he cites as example the bundle of His and Auerbach's and Meissner's plexuses, the former being the more complex; but recent researches (Ram  n y Cajal and Dogiel) have thrown some light on their structure. Bard concludes that the various nerve elements can furnish a complete reflex arc and illustrates this by the analogy of a vascular reflex, "which should be constrictor or dilator, as the impression which evokes it demands increased flow or restriction of the blood stream." Many other illustrations from the physiology of the central nervous system are given. Bard remarks that the intervention of the sympathetic, which plays a leading part in the production of morbid phenomena, shows itself chiefly by anomalies of reflex action, and concludes by referring to various drugs which exercise a powerful influence on the sympathetic—atropine, eserine, adrenaline, etc.—and especially on the contrasted action of digitalis and of quinidine. These few examples, collected from cardiac therapeutics, explain the importance of the preceding principles and the new aspect given to the great part of therapeutic problems pertaining to symptomatic medication.

272.

Intramuscular Injections of Ether in Whooping-cough.

T. SCH  NFELDER (*Tidsskrift for den Norske L  geforening*, August 1st, 1922, p. 650) has tested the efficacy of intramuscular injections of 1 to 2 c.cm. of ether in cases of whooping-cough at the Ullev  l Fever Hospital, and has found them remarkably effective in reducing the frequency and severity of the paroxysms. His review of the literature of the subject shows that Audrain read a paper on it at Havre on the day before war was declared. During the war this treatment fell into abeyance, but since 1919 several papers have been published on the subject, and most of them have been confirmatory of Audrain's claims. The injections should be given every day for the first three or four days, and later every other day. The intramuscular is preferable to the subcutaneous route, as the latter entails more pain; there is also the risk of necrosis of the skin following a subcutaneous injection of ether. Injected into the muscles in the upper part of the gluteal region, it is not painful for long, and the child usually falls asleep within half an hour. This treatment is also useful in bronchopneumonia, and there have been favourable reports on its action in cases of measles and scarlatina. But the results of the injections are most dramatically successful in uncomplicated whooping-cough; much debilitated children suffering from anorexia and vomiting, combined with paroxysmal cough, have been restored in a few days to almost complete health. In cases of acute adenoiditis, simulating true whooping-cough, these injections seem to be practically useless.

273.

The Importance of Hereditary Syphilis in Infantile Atrophy.

H. BARBIER (*Journ. de m  d. et de chir. prat.*, July 10th, 1922, p. 463) observes that until recently the atrophy of nurslings was confused with the so-called "gastro-enteritis." These patients suffer almost constantly from dyspepsia, upon which true enteritis is often grafted by accidental infection, but this has no direct connexion with the original disease. The infection attacks not only the intestine, but the skin and the respiratory tract. The wretched state of the patients increases the gravity of any infection, and the greatest care should be exercised in maintaining scrupulous cleanliness by sterilizing clothing, etc., to prevent any pyogenic infection, which may lead to adenitis, otitis, bronchopneumonia, etc. The underlying cachexia is due to one or both of the following conditions: (1) hereditary or congenital conditions, (2) environment (and alimentation). Of these, the first preponderate, and greatly aggravate the dangers of faulty hygiene, but the child of healthy parents may become cachectic if improperly fed, and may be cured if the mother resumes suckling. Barbier then discusses the biology of hereditary disease due (a) to intoxications, or (b) to infections. Among the toxic agents, he places alcohol first, then lead, mercury, phosphorus, morphine, and cocaine. Barbier states that infections act in two ways: (1) by toxic action on the sexual glands, or (2) by attacking the impregnated

vum. The most common infective diseases are tuberculosis, syphilis, and malaria. In regard to syphilis, 33 per cent. of 11 the author's cases had a positive Wassermann reaction, but others with negative reaction showed definite clinical symptoms (9 per cent.). Barbier therefore estimates that syphilis is responsible for 42 per cent. of all cases of infantile trophic. He states that these patients may often be cured very rapidly by specific treatment. He prefers arsenic compounds to mercury, and recommends subcutaneous injections of sulfarsenol, given in daily doses of 0.01 to 0.02 g. per kilo of body weight. The larger doses (up to 1 g. per kilo) that have been recommended by some writers he considers dangerous, at least at the commencement of treatment.

274. The Fate of Syphilitics with Salvarsan Rashes.

J. KLEINSCHMIDT (*Deut. med. Woch.*, July 21st, 1922, p. 981) refers to a paper by Buschke and Freymann, who re-examined 0 patients who had suffered from severe salvarsan dermatitis. With one exception these patients were found to be clinically well and Wassermann-negative, although the specific treatment had been incomplete. It was concluded from these cases that the reaction of the skin plays an important part in recovery from syphilis. With this conclusion Kleinschmidt disagrees. Since 1916 he has observed 19 cases of syphilis with severe toxic rashes. He included in this category only those cases which, at the beginning of antisyphilitic treatment, showed either an eruption on the skin or mucous membranes or a positive Wassermann reaction. Of the 19 patients, all of whom suffered from severe dermatitis, 7 showed a negative reaction after the outbreak of the rash. But a conversion of positive to a negative Wassermann reaction usually follows salvarsan treatment, so this serological change could hardly be traced to the dermatitis. All the other 10 patients continued to show a positive Wassermann reaction in spite of severe and general dermatitis, with oedema of the face and limbs, secondary furunculosis, pyoderma, and abscesses of the sweat glands.

275. Malarial Relapses.

I. H. HOWARD (*Southern Med. Journ.*, May, 1922, p. 343), from experience while directing an experimental campaign for the control of malaria by antimosquito measures, found that in 919 44.1 per cent. of the cases were relapses and 55.9 per cent. were new infections, while in 1920 the ratio was 61.3 per cent. to 38.7 per cent. respectively. Since a large percentage of malaria each year results from relapses from infections acquired in previous seasons the use of quinine in sterilizing carriers is indicated, seeing that the occurrence of relapses will continue whether mosquitos are present or not. On this count relapses become a limiting factor in malarial control by antimosquito measures alone, and lead to the obvious conclusion that the sterilization of carriers by quinine is an essential auxiliary to success in obtaining early and satisfactory results. The district investigated was divided into two areas—one, "the controlled," being that in which measures for the prevention of mosquito production were carried out, and the other, "the non-controlled," being that in which no such measures were adopted. Relapses occur with great frequency for long periods after the initial infection is acquired, so that the malarial morbidity rate of any given year is due largely to relapses from infections received in the previous year or years.

276. Pulmonary Blastomycoses.

VALUABLE general review on the subject of the blastomycoses is given by F. SERVET (*Rev. méd. de l'est*, June 1st, 1922, p. 364). The term may be defined as connoting those diseases which are due to the group of fungi known as the blastospores. These organisms are capable of invading any issue in the body. As regards the lungs two types of the disease may be distinguished: in the first there is a primary and exclusive localization of the parasite in these organs; in the second the pulmonary affection is secondary to a generalized blastomycosis. There is a very close similarity to tuberculosis, and there is little doubt that many of the cases have been wrongly diagnosed. From the pathological standpoint the essential lesion of the disease consists in small nodules, loosely resembling those produced by the tubercle bacillus, but differing from them in the greater readiness with which they break down into pus. The diagnosis is made by examination of the sputum, when, instead of the discovery of acid-fast bacilli, large round or oval yeast-like elements are found. In some cases the presence of a positive complement fixation reaction may be established, as also the existence of agglutinins in the patient's serum. Only occasionally can the organism be isolated from the blood. The importance of a correct diagnosis lies in the fact that there is generally a favorable response to treatment with potassium iodide; with the administration of large doses the disease often clears up in a few weeks.

SURGERY.

277. Early Signs of Cholelithiasis.

SIR BERKELEY MOXNIHAN (*British Journal of Surgery*, July, 1922, p. 127) states that probably many surgeons have operated upon cases where a diagnosis of cholelithiasis has been made and failed to find any gall stones present. Many of these gall bladders, however, may show signs of disease, a condition known as "strawberry gall bladder" perhaps being present, where the congested mucosa is studded with yellow dots ending at the cystic duct. The symptoms often diagnosed as gall stones may be due to an infection of the gall bladder, set up, it may be, by stones, but not seldom existing in the absence of stones. There are several channels by which invading organisms can reach the gall bladder: (1) Infection may ascend along the duodenum, but this mode of infection is probably rare. (2) Infection may descend from the liver, organisms reaching the liver by way of the portal stream. The portal blood comes from the alimentary canal and the spleen, and it is possible that in some cases organisms may come from the spleen. The association of disease of the liver and spleen has recently become clearer, and splenectomy may be found necessary for recurrent cholelithiasis in some cases. One function of the spleen is to filter out organisms and send them to the liver for destruction. It may sometimes harbour rather than destroy them. (3) Infection may be derived from the blood, as shown by Rosenow. Organisms may be found beneath the mucous layer, and calculi may originate there, and later detach themselves and become free in the gall bladder. (4) Infection may reach the gall bladder by the lymphatics of the liver. Affections of the liver have been often noticed in operations for gall stones. The view is held that cholecystitis is secondary to hepatitis. (5) Infection may reach the gall bladder by direct continuity. This method is rare. Gastric and duodenal ulcers may have the gall bladder adherent to them, and infection penetrate the gall bladder from its serous surface inwards. In cases where infection reaches the submucosa a considerable development of fat may be found beneath the peritoneum. A similar deposit may be seen over gastric ulcers and in the mesentery in chronic appendices or with diverticula of the colon. The symptoms of gall stones are early wholly referable to the stomach—flatulence and a fullness after meals, nausea accompanied by faintness, and often salivation. It is in the association of these symptoms that their importance lies. Sometimes pain and a slight enlargement of the liver may be present. It is likely that in many cases the liver is first involved, and the gall bladder attacked later by way of the lymphatics or by direct extension.

278. Methods of Drainage in Surgery.

BALSAMO (*Rif. Med.*, June 26th, 1922, p. 607), after a brief reference to old methods of treating collections of pus, divides modern methods of drainage into two main groups: (1) using substances supposed to possess absorptive power—for example, cotton-wool, threads, charcoal, catgut, sand, iodoform, sugar, etc.; (2) tubes which keep the channel open and allow the pus to escape within or along the line of the tube—of the various materials used rubber and gauze are the commonest. Cigarette drainage, introduced by Ruggi in 1897, is also used. Paraffin drainage, proposed by Sorel in 1915 (either *en bloc* or by strips of gauze soaked in paraffin), has given good results. Filiform drainage by means of horsehair or silk is especially useful in fistulous tracks. None of these methods give perfect satisfaction, and for some time the author has abandoned drainage in open surgical wounds and trusted to the use of thin rubber sheets. Fragments of old rubber gloves well holed are introduced to the bottom of the wound, packing loosely like a plug and using no strips of gauze. The author has treated in this way empyemata, appendix abscesses, and many other conditions, and is very pleased with the result. The pus flows out between the folds of rubber, and the change of dressing is simple and painless. The slight inconvenience of saturation or maceration of the skin by the pus may be partly avoided by smearing vaseline.

279. Operative Treatment of Scoliosis.

S. KLEINBERG (*New York Med. Journ. and Med. Record*, July 19th, 1922, p. 93), in a preliminary report, records his experience of an operative treatment of scoliosis by which it is hoped to obtain the same improvement as that following the more prolonged treatment in plaster jackets, and by fusion and splinting of the spine to retain such improvement and prevent any increase of deformity. The pre-operative stage consists of continuous extension or hyperextension on a convex stretcher frame, traction being applied to the head and pelvis, with, in some cases, lateral traction over the convexity. As soon as the maximum degree of reduction

has been obtained (usually in about eight weeks, as compared with many months with plaster) a fusion operation of the spine is performed by the addition to the ordinary Hibbs's fusion operation (which does not apparently always result in solid bony ankylosis) of a splinting of a number of vertebrae with a stout beef-bone graft, extending from one end to the other of a single curve, or of one section of a compound curve. Usually the graft is about eight inches long, and extends from the second or third to the twelfth dorsal vertebra, beef bone being used in order to shorten the time of operation. After Hibbs's fusion operation has been performed upon the most curved part of the spine, the spinous processes of the two uppermost and two lowest vertebrae of the section operated on are split, and the graft is laid on the laminae and transverse processes on the concavity of the curve and its ends embedded in the split spinous processes. The periosteum and muscles are sutured with kangaroo tendon, and the subcutaneous tissue and skin with catgut. The patient is put to bed and not on to the frame for the following week or ten days, after which he is placed on the frame and traction is applied to the head and pelvis for about eight weeks. A supporting brace, or plaster jacket, is then worn for about three to six months.

220. Tonsillitis followed by Fatal Peritonitis.

F. RIEDEL (*Deut. med. Woch.*, August 11th, 1922, p. 1075) records two cases, occurring in the same household, of tonsillitis followed by rapidly fatal peritonitis. The first patient was a servant, aged 48, who developed tonsillitis after getting wet. She was admitted to hospital on the second day of the disease with redness and swelling of the pharynx and a yellow-brown coating, thick and dirty-looking, on the tonsils and palatine arches. Diphtheria bacilli could not be found either in smears or on culture. The temperature was 104° F., and the glands in the neck were swollen and painful. After the reaction in the throat had subsided considerably and the temperature had begun to fall the patient suddenly developed severe diarrhoea and vomiting. The temperature rose to 103.5° F. and the pulse to 120, the abdomen meanwhile becoming tender and distended. Two days later free fluid in the abdominal cavity was demonstrable, and the patient died eight days after admission to hospital. A few cubic centimetres of pus were found in the right pleural cavity, and in the peritoneal cavity there was a large quantity of thick green pus, from which streptococci were cultivated. Three days after this patient fell ill a woman, aged 27, living in the same house, developed tonsillitis. The signs and symptoms were almost exactly similar to those of the first case, being, however, even more severe; the second patient died on the same day as the first, and in both cases a prominent feature was the great respiratory distress. The first patient had doubtless infected the second, and the increased severity of the disease in the second case was probably due to the virulence of the infecting organism having been increased in the course of transmission from the one patient to the other.

281. The Pathogenesis of Renal Tumours.

L. H. DERRICK (*Med. Journ. of Australia*, June 10th, 1922, p. 623), as the result of a study of 66 cases of renal and adrenal tumour, discusses the pathology of tumours of the kidney. The Wilms tumour of the kidney attacks infants, and in 75 per cent. before the age of 5. It is malignant, grows rapidly, and recurs after removal. These tumours show a combination of adenoma-like tubules with broad bands of indifferent spindle-celled tissue; smooth muscle and myxomatous connective tissue may also be seen. They arise through a disturbance of the normal development of the kidney. The Grawitz tumour or hypernephroma is the commonest tumour of the kidney; of tumours in adults it comprises about 80 per cent. It arises in all parts of the cortex, is rounded, and varies in size; it does not infiltrate the kidney, and has a fibrous capsule. Cysts are common; and it is yellow and red in colour, due to fat and haemorrhage. The typical cell is large with a small nucleus. Grawitz considered that these tumours grow from misplaced portions of adrenal tissue in the kidney. This must be rejected, the evidence being in support of its renal origin. The Grawitz tumour may be traced through the adenomata from the renal tubules, and it is entirely different from tumours in the suprarenal gland itself. Wilson asserts that the Grawitz tumours arise from rests of embryonal kidney tissue which remain undeveloped till they take on neoplastic properties. This suggestion, however, cannot be accepted, and the age incidence is inconsistent with the embryonic origin. Renal tumours may be divided into four great groups according to the type of cells: (1) an embryonal group, the usual form being the mixed tumours of Wilms; (2) the series of epithelial tumours, including adenoma and Grawitz carcinoma; (3) a heterogeneous group, mainly small and benign; (4) renal pelvis tumours, papillomata and carcinomata. In children the Wilms mixed tumour is found, in adults the Grawitz carcinoma.

OBSTETRICS AND GYNAECOLOGY.

282. Acute Infection in Syncytioma.

ACCORDING TO H. E. MELENEY (*Surg., Gynecol., and Obstet.*, 1922, p. 137), it is frequent, in cases of the more benign syncytiomata, with little tendency to formation of metastases to encounter an acute infection of the uterus leading in many instances to a fatal septicaemia or peritonitis. The persistence in the uterine of soft, vascular, and partially disintegrating tissue provides a favourable culture medium for bacteria which are accidentally present and leads to so-called "syncytial endometritis." In Schlauch's summary of 206 cases seven died of sepsis, and in all these the tumour was benign. It is important to establish an early diagnosis of the cause of persistent uterine bleeding after abortion or parturition, in order not only to deal properly with the tumour itself, but also to avoid acute general infection. The writer records a case of severe uterine haemorrhage persisting during twelve months after abortion; the patient died, apparently from septicaemia, after a short period of pyrexia unaccompanied by pain. At autopsy haemolytic streptococci were isolated from the blood, peritoneal cavity, and uterus; in the uterine cavity near the entrance to the right Fallopian tube was a small regressing syncytial nodule 1.5 cm. in diameter, which apart from the infection which terminated the case, would probably have disappeared. Pus was demonstrated microscopically in the vessels leading to the peritoneal cavity and in the general circulation.

283. Abdominal Pregnancy.

ACCORDING TO P. JACQUIN (*Gynecol. et Obstet.*, 1922, v. 6, p. 493) many of the cases reported as examples of primary abdominal pregnancy have been instances of tubo-abdominal pregnancy (the ovum being inserted on a portion of the tubal fringe), of pregnancy in an accessory Fallopian tube, or of secondary abdominal pregnancy coming late to operation at a time when traces of the original implantation have become difficult or impossible to find. Sittner and also Wolff have shown that in rabbits the foetus may reach full growth in a normal configuration at term, after experimental transplantation, at the eighth day of gestation, from the uterus to the abdominal cavity. For clear demonstration of the occurrence of primary abdominal pregnancy in the human subject it is important that the ovum examined should be living or recently detached and that macroscopic and microscopic examination should be made both of the site of insertion of the ovum and of the genital organs, especially the tubes and ovaries. Jaquin relates a case in which these conditions were fulfilled and which, he thinks, is with a considerable degree of certainty to be regarded as an instance of primary abdominal pregnancy. A 5-para, aged 32, was operated on for probable ruptured left tubal gestation with severe intra-abdominal bleeding; to the left and at the lower part of the pouch of Douglas an ovum measuring 2 by 3 cm. was implanted on the posterior aspect of the posterior wall of the cervix and had caused haemorrhage, from which the patient died two days later. The genital organs were examined microscopically in serial sections and showed no trace of recent uterine, tubal, or ovarian gestation. G. VALMALE and ROBIOLIS (*La Gynecologie*, June, 1922, p. 363) record the case of a primipara, aged 34, whose pregnancy, except for slight metrorrhagia, accompanied by prolapse of the cervix uteri was uneventful until the seventh month, when severe abdominal pain was experienced, lasting for ten days. In the eighth month an attack of intestinal obstruction occurred. At operation a living foetus was found developing external to the membranes, below the stomach and transverse colon. The mother succumbed a few hours later, but the child, which was free from deformities save unilateral talipes, appeared healthy at the age of 2 months.

284. Treatment of Puerperal Fever.

A. DÖDERLEIN (*Deut. med. Woch.*, 1922, xlviii, p. 22), after removing with forceps any retained shreds of foetal membrane, treats patients suffering from puerperal fever by injecting at low pressure into the uterus 1 litre of a solution of iodine or one of its preparations. Curetting and other forcible manipulations are to be avoided, and mercuric chloride or carbolic acid should never be used for uterine douching. In many cases the fever disappears after on lavage, but if streptococci are detected in the lochia and the pyrexia persists, injections of colloid and protein substance are given. Antipyretics are beneficial. Abscess in the parametrium should be opened, from the vagina when possible. Hysterectomy is contraindicated in cases of streptococcal infection, but may in certain other cases be performed with successful results. Ligation of the veins draining the pelvis may be beneficial in some cases of thrombophlebitis, but the choice of cases calls for very skillful judgement. The necessary abdominal drainage for suppurative peritonitis is best

lone by posterior colpotomy, which in over 70 per cent. of cases leads to cure. Coeliotomy via the posterior fornix is a useful diagnostic procedure; it is attended by little shock, and if pus is not found the wound can be closed by sutures.

285. Cardiac Failure during Pregnancy and Labour.

In the experience of H. E. B. PARDEE (*Amer. Journ. of Obstet. and Gynec.*, June, 1922, p. 620) mitral stenosis has been less dangerous than aortic regurgitation as a complication of pregnancy and labour. The prognosis is more grave when the cardiac decompensation is first manifested during labour, not during pregnancy. In such circumstances tachycardia, orthopnoea, cyanosis, pinkish frothy expectoration, and distension of the neck veins indicate impending cardiac failure and oedema of the lungs. The immediate treatment should consist in hypodermic injection of 1/4 grain of morphine and 1/50 grain of atropine, withdrawal of about 8 oz. of blood from a vein, and intravenous injection of 1/50 grain of digitoxin if the patient has not been previously receiving digitalis. If in spite of giving morphine labour continues to progress and if the morbid symptoms show no improvement, labour must be terminated. Version is attended by much shock and vaginal Caesarean section is too lengthy an operation, so that if a low forceps operation is not feasible abdominal section is probably the best method of treatment. The administration of ether, preceded by a little chloroform, throws less strain on the heart than is the case with gas and oxygen anaesthesia. When decompensation is first noted some weeks or months before labour, proper treatment usually leads to quick recovery, and most patients can be safely carried through to term or to labour induced during the eighth month; in such cases proper observation and prompt operation, if necessary, will usually prevent the occurrence of severe decompensation during labour.

286. Tears of the Tentorium and Falx during Labour.

R. ZIMMERMANN (*Münch. med. Woch.*, 1922, 3) classifies tears of the tentorium and falx produced during labour according as they are infratentorial, supratentorial, or mixed. Two of thirteen cases coming to autopsy were of the first-named group, and the writer believes that the clinical picture corresponding to infratentorial tears is a characteristic one; death of the child ensues immediately after the first respiration, the placental circulation being still intact. Probably the haemorrhage from the tear is insufficient to affect the respiratory centre until reinforced by the circulatory changes following the first respiratory effort.

PATHOLOGY.

287. Haemolytic Streptococci.

E. VALENTINE and C. KRUMWIEDE (*Journ. of Exper. Med.*, August, 1922, p. 157) had been using a culture of a haemolytic streptococcus for more than a year for the production of immune serum, and during this period it was subcultured at frequent intervals and no change in its characters was observed. When plated in April, 1921, however, it was found that 10 per cent. of the colonies showed no evidence of haemolysis, but resembled closely a pneumococcus colony. The two apparently different strains were obtained in pure culture, and since then have bred true for more than fifty transfers. Morphologically and culturally the strains showed no differences, except that one was haemolytic and the other non-haemolytic. Antiserum was prepared against each strain and showed that both fractions were agglutinated equally well, and that absorption of serum by either fraction removed completely the agglutinins for both fractions, thus showing that the loss of haemolytic power had not been accompanied by any change in the agglutinogenic complex of the cocci. Virulence tests revealed the fact that the haemolytic variety was more pathogenic for mice than the non-haemolytic. It was not found to be possible to restore haemolytic properties to the non-haemolytic strain by increasing the virulence by mouse passage or by successive cultures in blood broth. Variations in the physiological functions of bacteria occur with frequency, which has given rise to the impression that the fundamental antigenic constituents are also readily subject to change. But general experience indicates a high degree of stability of bacterial types as regards the antigenic qualities of the body substance, indicating that a change in antigenic constituents is a fundamental and radical change, and therefore an unusual occurrence. This study offers additional evidence in favour of the hypothesis that functional changes among bacteria are only very infrequently associated with changes in the antigenic matrix of bacteria.

288. Effect of Artificial Pneumothorax on General Nutrition and Growth.

THE modification of the respiratory exchange produced by artificial pneumothorax induced J. PARISOT and H. HERMANN (*C. R. Soc. Biologie*, June 17th, 1922, p. 177) to study the effect of the functional suppression of one lung on the general nutrition. For this purpose two sets of experiments were conducted—one dealing with adult rabbits, the other with young growing rabbits. In the first series it was found that subsequent to the operation the animals lost weight to the extent of about 10 per cent.; at this level they remained relatively stable. *Post mortem* the most striking point was the disappearance of the fatty reserves of the body, especially those around the kidneys. In the second series artificial pneumothorax was performed on rabbits 1 month old, and their growth curves compared with those of control animals of the same litter. Both as regards weight and size the animals which had been operated on increased at a slower rate than did the controls; this difference was retained throughout the whole period of development till, at the end of seven or eight months, when growth had practically ceased in both sets of animals, there was a striking dissimilarity noticeable. At the autopsy the experimental rabbits were found to have laid down no fat reserves at all. It would seem, therefore, as if the effect of artificial pneumothorax was to increase the rate and extent of fat metabolism in the body; the explanation of this the authors hope to bring forward in an approaching publication.

289. Diagnosis of Organic and Functional Meningeal Conditions by Pandey's Reaction.

M. M. WEILL, A. DUFOUR, and H. CHAHOVITCH (*Lyon Medical*, June 10th, 1922, p. 842) state that it is often impossible by clinical examination only, particularly in infants, to differentiate between actual meningitis and a functional meningeal disturbance. Clinically, certain forms of meningitis are extremely latent, while there are patients in whom the violence of functional meningeal reactions leads to a diagnosis of a meningeal lesion which does not exist. The quantitative analysis of the fluid and a leucocyte count require certain laboratory apparatus, while the simplicity, rapidity, and accuracy of Pandey's test have led the author to adopt it during the last year in the examination of forty specimens of normal or pathological cerebro-spinal fluid. The technique is as follows: (1) Dissolve 10 grams of pure phenol in 150 c.cm. of distilled water. (2) Pour 1 c.cm. into a small test tube and allow one drop of the fluid under examination to fall into the solution. If the reaction is negative no change occurs; if positive, a bluish-white cloud appears, which descends spirally to the bottom of the tube, and finally discolours all of the fluid. It is a quantitative reaction, and due to precipitation of albumins in the cerebro-spinal fluid. The author's results are as follows: 18 cases of tuberculous meningitis, 1 of acute syphilitic meningitis, 5 of cerebro-spinal meningitis, 1 of meningitis following spinal anaesthesia, 12 cases of "meningismus." In all cases in which definite meningitis developed the reaction was positive at the first examination. The 12 negative cases were subsequently found to be free from meningitis—they were functional reactions occurring in the course of pneumonia, enteric fever, influenza, etc. Pandey's test always agreed with other chemical tests of the cerebro-spinal fluid, and proved to be most valuable in cases of babies and young children.

290. The Thyroid Gland and Sensitivity to Tuberculin.

L. KEPINOW and S. METALNIKOW (*C. R. Soc. Biologie*, June 24th, 1922, p. 210) have been working out the relation of the thyroid gland to tuberculin sensitization in infected animals. Four thyroidectomized guinea-pigs and four controls were given a very virulent culture of living tubercle bacilli subcutaneously. A month later they were injected with tuberculin, two of each set being given a lethal and two a non-lethal dose. In the control animals the temperature rose from 1.5° to 1.8° C., and two of them died. In none of the animals whose thyroids had been removed, however, did the temperature rise more than 0.6° C., even in the two which died after receiving a lethal dose. From this it would appear as if two distinct phenomena were being dealt with: one which may be classed amongst the anaphylactic reactions and which depends for its appearance on the integrity of the thyroid, and one which is purely toxic and which bears no relation to this gland. In a second series of experiments they found that, by injecting the serum of a tuberculous guinea-pig into a normal animal, it was possible to sensitize the latter to the febrile factor in tuberculin, but not apparently to the toxic factor. If, however, the serum of a tuberculous thyroidectomized guinea-pig was used for preparing the normal animal, there was no passive transmission of either factor.

The Harveian Oration ON MEDICINE IN THE CENTURY BEFORE HARVEY.

BY
ARNOLD CHAPLIN,

HARVEIAN LIBRARIAN OF THE ROYAL COLLEGE OF PHYSICIANS
OF LONDON.

MR. PRESIDENT, FELLOWS, LADIES AND GENTLEMEN,—In obeying the command of your predecessor to deliver the Harveian Oration I desire, Sir, to record my deep sense of the great honour bestowed upon me, and of the diffidence I experience in approaching a task that has occupied the abilities of so many distinguished men in the past. Already two hundred and two Orators have complied with the conditions formulated in Harvey's bequest. The subject has been presented from many aspects, and I should be guilty of an act of presumption were I to suppose that any part of the field had escaped the minute investigation of so many acute intellects.

Harvey, when founding this oration, indicated with great precision its aims and its extent, but the provisions elaborated with such care by the founder, have been interpreted by successive orators in various ways. Sometimes the orator has obeyed the injunctions of Harvey more or less literally, while at other times a brief reference to the commands of the founder has sufficed to link them to the subject of the oration. But Harvey desired this oration to be, above all, the medium of an annual exhortation to this College for the express purpose of keeping alive in the minds of the Fellows certain important principles for the guidance of their conduct in private and professional life—principles as worthy of acceptance to-day as they were in the seventeenth century. For this reason I am constrained to call attention to the commands contained in Harvey's bequest, for they form the essence of the creed of all honourable physicians whether ancient or modern.

These commands of Harvey may be considered for a moment with reference to the manner in which they have been modified to meet the needs of modern times. The founder ordained that this oration should be delivered in Latin, but that tongue has not been heard on this occasion since 1854. The Latin language has ceased to be the usual method of communication between the learned, and by common consent that injunction has been allowed to fall into abeyance. The second injunction imposes upon the orator the duty of mentioning by name all the benefactors of the College, of recounting the work they have accomplished, and of exhorting others to emulate them. But here again the lapse of years has swelled the roll of those who have benefited the College to such an extent that the time at the disposal of the orator would hardly permit him to comply with the command. A judicious selection of names, therefore, is all that the orator can attempt in obedience to this act of piety demanded by the founder. The two remaining injunctions, requiring us "to search and study out the secrets of Nature by experiment; and also for the honour of the profession to continue in mutual love and affection," present no difficulty to the orator of the twentieth century, for they comprise the whole duty of the physician in every age in which his life is passed. But when Harvey in 1656 attached to his bequest these two fundamental commands the peculiar condition of political and scientific thought rendered them specially imperative. The experimental method in science was then in its infancy, and many physicians still clung obstinately to the teaching sanctioned through centuries by authority, itself based on insecure foundations. Political and religious feeling ran high in the seventeenth century, and the admonition "to continue in mutual love and affection" became the solemn duty of every man who had the welfare of the College near to his heart. Although no direct evidence exists in support of the contention, it is impossible to believe that some echo of the fierce political and religious passions then raging in England was not heard within the walls of the College. For the College contained in its body men ready to die for the king, and men just as ready to send that king to a shameful death; men to whom the surplice was an abomination, and men who sighed for the days of universal

orthodoxy, before King Henry VIII had raised his destroying hand. All honour, then, to this College for the restraint it was able to exercise, so that, while Puritan and Royalist were engaged in a deadly struggle, the Fellows, holding the same divergent opinions, were able to meet and conduct their business with such decorum that history has been unable to record any overt act of enmity. The amount of control needed may be imagined when men like John Bathurst and Laurence Wright, both in Cromwell's service and high in his favour, took their seats at the Comitia side by side with Harvey and Sir Charles Scarborough, who were no less zealous in the service of their king. May such moderation be an example for all time!

This College, since its foundation in 1518, may be regarded as representative of medical thought in this country, for, with few exceptions, those who have contributed to the advance of the science and art of medicine have been members of its body. But of all those who have conferred honour and distinction upon the College by reason of their additions to our stock of scientific knowledge William Harvey occupies alone the place of honour. His great work, in which he gave for the first time the true explanation of the manner in which the blood circulated, was published to the world in 1628—110 years after the foundation of the College. The appearance of that work marked the beginning of the epoch of modern physiology, and the close of the long period during which the authority of Galen had held undisputed sway. After the publication of the *De Motu Cordis* the scales fell from the eyes, and men broke for ever with the old and inept tradition that had for centuries hindered the advance in scientific thought concerning biology. But however far-reaching the influence of Harvey's great work may have been, it must not be forgotten that it was but one of the epoch-making movements taking place at the same time in other branches of science. For the early years of the seventeenth century witnessed the gathering of the first-fruits from that vast change produced largely by the revival of learning—a change which ended mediaevalism and freed the human mind from the fetters of blind adherence to authority.

In my attempt to comply with the conditions laid down in the bequest of Harvey I propose to direct your attention to a consideration of the history of medicine and science during the first hundred years of the existence of this College, or up to the date of the appearance of Harvey's work. In carrying out that project it will be my duty to indicate briefly the chief causes responsible for the decay of the Middle Ages and the revival of letters in the rebirth of the study of medicine and science I hold to be a part of that wonderful change. I shall then pass to a review of the state of medical and scientific knowledge during the sixteenth century, or up to the appearance of Harvey's work in 1628. Finally, I shall offer some considerations concerning the change wrought in medical and scientific thought during the seventeenth century by the advent of Harvey. In adopting this method I shall be able to select from the roll of the College types of mental activity in illustration of the various phases through which medical thought passed during the period under review.

THE AGE OF AUTHORITY.

Until the dawn of the sixteenth century, coeval with the foundation of this College in 1518, it might be asserted that the study of medicine had made little advance in Europe since the Greek period, which closed with the age of Galen. For more than a thousand years, therefore, the world was content with a medical system constructed in ancient times. But it was not medicine and science alone that failed to register any advance; for the study of all branches of learning was involved in the same black night of stagnation and obscurity, and as age succeeded age Europe receded farther and farther into the abyss of ignorance and intellectual sloth. The chief cause for this lamentable state of learning in Europe was political, and really began on the day when Constantine the Great, in 323, spear in hand, followed the invisible heavenly guide in marking out the limits of the city of Constantinople, the future capital of the East. Although the great founder fondly hoped to rule both East and West while established on the fair promontory at the entrance of the Bosphorus, it soon became evident that the two empires must separate and accomplish their destinies in their own appointed ways. By the time that the great Theodosius was carried to his grave in 395 the division of the empires, begun

in 364, was complete, and the Greek influence was confined to territories along the shores of the Bosphorus, the Propontis, and the Eastern Mediterranean, with stately Constantinople as its diadem. As time proceeded, Greek thought, learning, and language became more and more circumscribed within the over-narrowing limits of the Eastern empire, and the little progress their influence made was entirely in the direction of the east and south. Meanwhile the Western empire in Europe steadily discarded the Greek influence until scarcely any vestige of it remained. To all but a few the Greek tongue in Europe was unknown. Barbarians occupied the throne of the Caesars, and a crude system of theology prescribed the limits of knowledge, beyond which the minds of men were forbidden to venture. From time to time half-hearted attempts were made to revive Greek thought in the West, but the result was transient, and the dark cloud of ignorance and indifference settled down once more.

Yet it must not be supposed that all learning was dead. The classics were still read in the West, but the knowledge they contained was closely guarded by the religious houses, and was the appanage of their inmates alone. The Church soon became aware that its power, both spiritual and temporal, required support that could be obtained only by an appeal to the intellect. In response to this demand, in the eleventh century was laid the first foundation of that system of learning known by the name of "Scholasticism" which has amazed and, perhaps, appalled the intellectual world ever since. In support of the tenets of the Church the aid of metaphysics borrowed from Aristotle was invoked, and a system was reared having for its basis certain principles founded upon the authority of antiquity which it was sacrilegious to impugn. For centuries intellectual Europe was engaged in the barren task of commenting upon those principles. They could not be submitted to destructive criticism, for to doubt or to inquire entailed pains and penalties in this world and in the world to come.

THE REVIVAL OF LEARNING.

But although Western Europe was unacquainted with the Greek tongue at this time, it was nevertheless possessed of a knowledge of the writings of the Greeks by means of translations into Latin through the medium of Arabian and Syrian translations from the original Greek texts. Through the same tortuous channels the medical writings of the Greeks were brought to mediæval Europe, were appropriated by the "schoolmen," and were subjected to the empty and narrow methods of the commentators. Meanwhile the Eastern empire was slowly dwindling, and its limits were gradually becoming confined to a small area with Constantinople as its centre. But, as Philocephus has said, in that peerless city the Court and the Church still spoke the language of Aristophanes and Euripides, and the libraries were still stored with the priceless manuscripts of the learning of ancient Greece. Although the Greek tongue was lost to Europe, and although the Eastern empire was becoming every year a more and more circumscribed civilization, two events were about to take place which may be regarded as first steps towards the restoration of the Greek spirit in the West. I refer to the Crusades, and the occupation of Constantinople by the Franks for a period of nearly sixty years. From the fervent pages of Anna Comnena we are made acquainted with the astonishment of the first Crusaders when, with predatory eye, they beheld for the first time the Greek capital in all its luxury and glory. We know also how frightful was the spoliation to which that fair city was subjected by the Franks when, in the name of the Master which both contending parties served, they marched through blood to its capture. It is, however, impossible to suppose that the visits of the Crusaders and the occupation of the city by the Franks did not contribute to the diffusion of the Greek spirit in the West.

The final act which unlocked the treasures of Constantinople and gave to Europe a full knowledge of Greek learning came in 1453, when on that fateful 29th of May Mahomet the conqueror burst through the gate of St. Romanus over the corpse of the valiant Constantine, and the Greek Empire ceased to exist after a thousand years of mingled glory and shame. Christendom has rightly deplored the last act of that tragedy when the Crescent supplanted the Cross at Constantinople. But the historian records with satisfaction that out of the evil thus perpetrated untold good

came to Europe. With the final overthrow of the Eastern empire the treasures of Greek learning were released, and became quickly disseminated throughout Europe. The Greek scholars fled and took up their abode in Italy. Ships coming from the Golden Horn carried the priceless manuscripts which the Turk, caring nothing for the learning of the infidel, had spurned. Italy received with kindness the scholar-refugee and his literature. The vanguard of those who were destined to restore the Greek spirit to Europe had already settled in that country, and soon the Italian universities were busily engaged in imbuing themselves with the new influence. Thither flocked students from every part of Europe, and among them one reared by this College, Thomas Linacre, our great founder. Scholasticism was swallowed up in the advancing tide of Humanism; learning revived, and with it medicine and science began to be studied again in a manner calculated to produce solid and lasting results.

Now if acquaintance with the condition of medical knowledge previous to the revival of learning be desired no better book can be consulted than the *History of Physics* written at the beginning of the eighteenth century by that admirable and learned Fellow of this College, Dr. John Freind. This work was composed in 1723, while Freind was lodged in the Tower under political suspicion, and does the greatest credit to his scholarship and vast knowledge of the medical writings of the ancients. In point of style the work is excellent, and although the first book to appear in this country dealing with the history of medicine, successive historians have been able to add little to our stock of knowledge of the subject. Freind's lively wit and the mastery of an easy style enabled him to present the history of medicine in a garb most acceptable to the reader. In a delightful vein of sarcastic pleasantry, worthy of his friend Swift in his happiest mood, he deals with the pretensions of many so-called medical authorities during the Middle Ages. From a study, then, of the pages of this Father of the History of Medicine in this country a clear view of the state of medical knowledge in the Middle Ages may be obtained, and Freind is fully worthy of being commemorated this day as a benefactor of the College, as a man of letters, and as a physician.

The condition of medical and scientific knowledge in the Middle Ages, as described by Freind, may be summed up in a few words. With the intellectual stagnation existing at that period in every branch of thought, progress could not be expected. Whatever mental energy was expended had for its aim the foundation of immutable principles that time and the ingenuity of the intellect could never alter. The learned might explain, but they might not criticize. Whatever had received the sanction of authority became a fixed belief, and steps were taken to protect it from doubt and destructive criticism. In fact, the ultimate end of all intellectual effort during the period of the Middle Ages was teleological, and so long as that spirit remained dominant no real advance in any branch of learning could be possible. All the knowledge that the Middle Ages possessed concerning medicine and science came from the Greeks, and even this was presented in an incomplete and inexact form. Through translation and repeated copying numberless errors had found their way into the classics, and it became a matter of no little difficulty to correct and purge them. How manifold were these errors will be understood when it is remembered that Hermolaus Barbarus restored no less than two thousand corrupt passages in the thirty-six books of Pliny. The Middle Ages, previous to the revival of learning, represented, therefore, a stationary period in which, as Whewell has justly observed, learned men could be produced, but not discoverers.

But with the revival of learning in the fifteenth century came a far-reaching change in the attitude of students towards the study of medicine and science. Hitherto they had been content to accept what had been sanctioned by authority. They were not competent to determine whether the texts they read were exact translations from the original or merely corrupt compilations by ignorant scribes. The recovery of the Greek tongue transferred medicine from men of this class to physicians deeply versed in classical knowledge, who combined the study of humanism with that of medicine and science. Their examination of the Greek texts enabled them to detect the violence that the translators had committed in their corrupt translations. These humanist or scholar-physicians loomed large in the first half of the sixteenth century, and it has been the desire of some to treat their work with scant respect. But let us remember that

without their aid it would have been impossible to revert to the original Greek texts, that they threw off the yoke of the Arabian translations and enabled students to go with safety to the Greek fountain-head of medical knowledge.

Many of the scholar-physicians had acquired their knowledge of Greek in Italy, where the study of that language had reached a high degree of perfection. But of all those who made a pilgrimage to the shrines of the new learning in Italy the great figure of Thomas Linacre, the founder of this College, and the best example of the scholar-physician, possesses for us an absorbing interest. It will not be necessary for me to recount the main facts of his career, and indeed to do so in this College, his ancestral home, would be an act of impiety. But I may with propriety comment upon certain features of his life and activities in order to assess the enormous debt this country owes to his learning, and to his efforts to improve the condition of medicine. Already proficient in the Greek language, through the influence of his friend and master, Selling, he travelled to Italy for the purpose of placing himself under the best teachers of the classics. Arrived there, he sat at the feet of Politian, to whom he owed his exquisite taste in Latin composition, and of Chalcondylas, who refined his knowledge of Greek. But while engaged in the pursuits of classical knowledge his thoughts became directed to the study of medicine, and after a residence of a few months at Padua he graduated in medicine at that university. Linacre had spent two years only in Italy, and some have pointed to this short preparation as evidence that the exercises for the degree were merely perfunctory. But in those days a knowledge of medicine as taught by the ancient writers was all that was demanded for the degree of doctor, and Linacre, we may be sure, while studying Greek and Latin, had become fully conversant with the medical texts, so that he could perform with ease the exercises required.

The writings of Galen appear to have attracted him most, for in after-years he confined his attention to that author, and devoted his unrivalled scholarship to the purpose of providing correct and elegant Latin translations of his more important works. The success of these translations was great, and largely owing to their popularity the authority of Galen became paramount during the early part of the sixteenth century. Indeed, so sacred was the teaching of Galen during part of the century that John Geynes, a Fellow of this College, was fined and threatened with expulsion for daring to impugn his authority. These translations of Linacre showed a distinct advance when compared with similar writings during the Middle Ages. They were not commentatorial, but merely good and exact translations from the original Greek, and enabled students of medicine, probably for the first time, to read Galen untrammelled by the useless and prolix commentaries of inexact and mediocre translators. After a perusal of these correct translations came the inevitable scientific sequoae of doubt and inquiry.

But to Linacre belongs a glory far in excess of any he obtained as a scholarly translator. Even the solid basis on which his fame rests as the first to revive letters in this country must yield to the position he occupies in our hearts as the great founder of this College—the first institution devoted to the conservation and advance of medicine in this realm. He had visited Italy, then the only place where the influence of the revival of learning was felt. In the various universities where he had pursued his studies, and where he had consorted with men of learning, he was impressed with the manner in which facilities were afforded for the prosecution of the quest for knowledge in all its branches. Padua, then nearing the zenith of its influence, must have had a profound effect upon his mind. No doubt he compared these busy centres of learning with Oxford and Cambridge, still slumbering in the heavy and uninspiring atmosphere of sterile scholasticism. In Italy he felt intellectual life vibrating, and saw men striving to climb the heights unobscured by the revival of learning. In England he remembered only the droning of the commentators, the unprofitable exercises, and the thunders of the nominalists and realists. While preparing for his degree in medicine at Padua he had seen the attention paid to that subject. The care bestowed upon the study of medicine by the universities and the State in Italy sank deep in his mind, and when in after-years he resolved to improve the condition of physic in his own country it was after the Italian model that he shaped his College of Physicians. England had her universities devoted

to learning, and now, through the inspiration of Thomas Linacre, she was to have her College of Physicians specially designed to guard the interests of physicians and to promote the study of medicine.

THE SCHOLAR-PHYSICIANS.

To Linacre, the scholar-physician, then, we owe it, and to him alone, that England soon after the revival of learning possessed a College endowed with adequate powers to guide and direct medical progress. The influence of that corporation upon the medical destinies in this country has been great. Throughout the course of centuries the College has retained the characteristics, indelibly impressed by the founder, of high purpose and catholicity of aim. For these reasons we of this College honour this day Thomas Linacre as the founder of our College of Physicians.

But the influence of Linacre bore fruit in other directions. With his friends Greyn and William Latimer he was responsible for the introduction of the revival of letters in this country. Without that revival the scientific achievements of the seventeenth century could scarcely have been accomplished. Finally, towards the end of his life he designed a scheme for the promotion of the study of medicine in the sister universities, and although the practical application of that scheme fell far short of the intention of the founder, the credit for the idea belongs to Linacre. Indeed, it would appear that in these latter days the desire of Linacre to improve the facilities for the study of medicine in the universities is at last meeting with its reward. At Oxford the funds of the Linacre lectureships are now devoted to the teaching of physiology, while at Cambridge you, Sir, as the occupant of Linacre's chair, have been worthily entrusted with the pious duty of promoting the aims so earnestly desired by the founder.

Less than half a century had elapsed since the death of Linacre before the destinies of the College were placed in the able hands of another scholar-physician, John Caius, a worthy successor of the founder. But for his energy and perseverance it is probable that the influence of the College as a factor in medical progress would have been confined within narrow limits. Caius, like Linacre, was a scholar. He had trodden the same path in his quest for learning in Italy. Taking the founder as his model, he spent his life in promoting the cause of learning and medicine. His benefactions were conspicuous, and whether he was designing the regulations of the College which bears his name, or ruling over this institution as its President, his aim was ever the advancement of knowledge. Although a true type of the scholar-physician, he was the first in this country to write a treatise on clinical medicine, and his short work on the sweating sickness is the precursor of the work of Sydenham and Heberden. Natural history also claimed his attention, and with Edward Wotton, a Fellow of this College, he shares the honour of being one of the first to write on that subject in this country. Of the thoroughness of his work for the promotion of the interests of this College we have abundant evidence in the first volume of the *Annals*, written in his own hand. To the most minute detail he ordered everything, from the compilation of the first book of Statutes to the provision of the silver caduceus still in use, and his pious act in rescuing from neglect the tomb of the founder. In common with Linacre, Caius was strongly attracted to the writings of Galen, and spent much of his time when in Italy in making a careful examination of the manuscripts of that author. But his scholarship, although profound, was not cast in such a rigid mould as that of Linacre, and there is evidence that his mind was undergoing the emancipation inevitable with the ever-widening scope of learning taking place in his day. When in Italy he lodged with Vesalius, and from this association it is probable that he acquired his taste for anatomy. In after-years, when he refounded Gonville Hall, the study of anatomy received full recognition in the regulations of the College. He also lectured on anatomy before the Barber-Surgeons, and may thus be regarded as the founder of the study of anatomy in this country. For this, and his unselfish devotion to the interests of the College, we record our thanks this day.

Caius may be regarded as the last conspicuous example of the scholar-physicians, and it will not be out of place to attempt an estimate of the work they accomplished in the cause of medical progress. These men were deeply versed in all the learning of the age in which they lived, and their knowledge of medicine came to them in the ordinary course

What was this theory of the circulation of the blood, and its consequent rôle in the nutrition of the body, as advanced by Galen? At the risk of repetition it must be stated in order to appreciate the great induction of Harvey. Galen's explanation, which I summarize from an admirable description recently given by Dr. Charles Singer, was as follows: "The food taken into the body became converted into chyle in the intestines, and was carried by the portal vein to the liver, where it was changed into blood, becoming there endowed with the essence of all living things, called 'natural spirits.' The blood thus manufactured and endowed by the liver was then carried by the hepatic vein and the vena cava to the right side of the heart. Here it was purged of its impurities, which found egress by means of the pulmonary artery and lungs to the external air. Then the venous blood thus purified ebbed to and fro in the veins and carried on the functions of nutrition. But a small portion of this venous

blood filtered through the septum of the heart by means of invisible pores into the left ventricle, where it came into contact with the external air which had reached that chamber by way of the trachea, the lungs, and the pulmonary veins. By this contact with the air and the innate heat of the heart the blood became endowed with a higher form of spirit, termed the "vital spirit," and became arterial blood, which, ebbing and flowing in the arteries in the same way as the venous or crude blood, carried on its higher functions of nutrition. But the arterial blood which flowed to the brain became endowed there with the highest form of essence, known as the "animal spirits," and was distributed to the body by means of the nerves, which were held to be hollow canals.

The main supports, therefore, of the hypothesis of Galen were the liver as the source of the veins and the blood; the communication between the right and left sides of the heart through minute and invisible pores in the septum; the presence of three vitalizing essences; and the absence of any circular movement of the blood propelled by the heart. This system, partly based on anatomy and partly on hypothesis, was accepted by the world for more than a thousand years. It postponed and fettered any advance in physiology, and on biological sciences generally imposed restrictions similar in effect to the theory of phlogiston on chemistry.

After Vesalius had broken the ground, anatomists who had sat at his feet carried forward his work until by degrees most of the supports of the Galenic hypothesis were weakened. Serretus, Columbus, Caesalpinus, and Fabricius contributed to the work of destroying the Galenic theory of circulation, but although they gave indications of the coming light they all lacked the power to draw the all-supreme conclusion. The complete demonstration of the manner in which the blood circulated and nourished the tissues required the work of a genius, and that genius was William Harvey.

In one short work, in size little more than a tract, he proved by a direct appeal to the phenomena of nature that the teaching of Galen concerning the circulation was wrong. He laid the sure foundation upon which almost the whole of our modern conceptions regarding physiology are based. In the history of scientific thought he takes his place beside Copernicus, Galileo, Newton, Lavoisier, and Darwin. By the intuition of genius he was able to sweep away false ideas and systems grown sacred by lapse of time and in their place to implant sound views acquired on the journey from scepticism to inquiry. Then the book in which Harvey expounded his theory is a model of close and accurate reasoning. Step by step each position is made secure before a new proposition is demonstrated. The whole is then welded together and the inference drawn. Harvey once remarked with a sneer that Lord Bacon wrote philosophy like a Lord Chancellor, and yet the *De Motu Cordis* is perhaps the most perfect example of the inductive method as enunciated by Lord Bacon's vast intellect. Indeed, it is hard to believe that Harvey, who knew Bacon well, was not influenced to some extent by that capacious mind.

Harvey, then, established the primacy of the heart as a muscular organ propelling the blood in the action of circulation, and explained how the blood found its way from the right to the left side of the heart. When these important facts were made secure the whole of the physiological doctrine of Galen fell to the ground, and the science of physiology was left free to pursue its logical course. It would be wrong, however, to assume that these revolutionary views found instant acceptance, for it could not be expected that a system that had endured for centuries would cease to exist without a struggle. For a time efforts were made to seek a compromise between the old and the new physiology. Even Harvey could not altogether emancipate himself from the glamour of the great name of Galen, and throughout his work, which was directed to the subversion of the ancient authority, he always treats him with respect. But eventually Harvey's doctrine became supreme, and by the time that he was carried to his grave in 1657 all but an insignificant minority accepted his views without reservation.

It has sometimes been assumed that the advent of Harvey's book at once displaced the whole of the system of Galen, including his medical teaching. This conception of the effect of Harvey's work is far from the truth, for, as a matter of fact, it had but slight influence upon the practice of medicine during the seventeenth century. The reason for this will not

be far to seek when it is remembered that modern physiology began with Harvey, and had to make considerable advances before it could be of real assistance to medicine. A long and distinguished line . . . with Haller towards the middle of the . . . I to accomplish their work before physiology was able to come to the aid of practical medicine. The science of chemistry, also, was uncreated, and it was not until the end of the eighteenth century that it was in a position to lend its powerful aid in the study of medicine.

The impetus given to the investigation of the problems of physiological science by the appearance of Harvey's work was truly marvellous. Before his day scarcely any attempt had been made to approach the subject from a rational point of view. But after the advent of the *De Motu Cordis* the progress of physiology was triumphant and steady. When we think of the successful labours of Aselli, the discoverer of the lacteals; of Borelli, who brought to the subject the new physics established by Galileo; of Malpighi, the father of our knowledge of the glands and the tissues; of Glisson, who first enunciated the doctrine of "irritability"; of the work of Willis and Lower, we can only be amazed at the advance made in a short time largely through the inspiration of the work of William Harvey.

This College justly acclaimed Harvey as its brightest ornament and conferred upon him its most signal honours. His work supplied the incentive to several fellows who, adopting his methods, contributed in no small degree to the enlargement of the boundaries of scientific knowledge. Among those who followed Harvey's precepts in the period immediately succeeding the appearance of his book I record the names of Francis Glisson, Thomas Wharton, Thomas Willis, Richard Lower, William Croone, Nehemiah Grew, Edward Tyson, and Clopton Havers, all of whom are worthy of mention on this day for the work they accomplished for science. But the teaching of Harvey left the majority cold, and did not exert any considerable influence upon their methods of investigating disease. Throughout the seventeenth century physicians were content to inquire regarding morbid phenomena in their studies, rather than at the bedside, until they were aroused from their speculations by the work of a man who stands pre-eminent in the annals of the College: I refer to Thomas Sydenham.

SYDENHAM.

Among the successors of Harvey the name of Sydenham finds a distinguished place. But, great as he was, by no exercise of the imagination can he be regarded as being influenced by Harvey's epoch-making work. Nor can he be properly admitted to the circle of men who fashioned the distinctive type of seventeenth-century thought. He stood alone in his glory. Knowledge gained from books he despised. The first-fruits of science garnered so marvellously in the beginning of the century were neglected by him, and even the new teaching of anatomy and physiology found him unresponsive. Indeed, except for a great admiration for the work of Bacon, we can hardly point to a single fact warranting us to link him with the spirit of the age in which he lived. He clung tenaciously to the humoral pathology and was uninfluenced by all the vast changes taking place around him. He was not a scholar; he had a contempt for science, and yet, in spite of these defects, he has left upon medicine in the seventeenth century an impression that will last as long as mankind requires medical aid.

Sydenham was essentially an innovator. He lived in the seventeenth century, but was not of it, and while others were painfully exploring the road of scientific advancement he, with the Father of Medicine as his only guide, fashioned his own path and for all time laid the foundation of clinical medicine. He was eminently fitted for the task of introducing new methods with the stern and vigorous Puritan blood in his veins; a real rebel; a fearless iconoclast. He was the first of a long line of distinguished physicians who raised the art of clinical medicine to its highest pitch. This country has always been renowned for its great clinicians, and the position to which they have attained has been due almost entirely to the influence of the teaching of Sydenham. If it should be asked what effect that teaching had upon the art of medicine, the answer would be given correctly by pointing to the work of Heberden, Bright, Addison, and Watson. His method was scientifically sound, and while others were attempting to make signs and symptoms conform to theory and authority Sydenham went straight to the

bedside to gather facts and make observations. In this he was true to the inductive method: a collector of facts from which to induce general principles.

Puritanism in the seventeenth century produced its Cromwell, the embodiment of relentless energy and resistless brain force; its Milton, who showed to what heights of grandeur and majesty our own dear language can attain; and its Bunyan, who, all unlettered as he was, in the simplest and sweetest vernacular panned the finest allegory the world will ever read. To these great productions of Puritanism may we not with justice add the name of Thomas Sydenham, the great Puritan physician, who founded for all time and for all countries the art of clinical medicine.

CONCLUSION.

Neither time nor the scope of this oration permits us to pursue further the immediate and remote effects of Harvey's work. Enough, I trust, has been said to show the comparative dearth of scientific endeavour before the date of his work, and the stimulus scientific research received on account of its appearance. In common with all other results of genius, attempts have been made to claim for others the honour of priority in promulgating the central ideas contained in Harvey's book; but they avail nothing. Copernicus was not the originator of the heliocentric theory, and Darwin gave to William Charles Wells the credit of having enunciated first the theory of evolution. But their glory is not diminished by these admissions, for ideas without irresistible proof are often the common property of the human intellect.

I do not propose to detain you with a consideration of the work of Harvey concerning generation, for that subject was dealt with last year in a most able and exhaustive manner by Dr. Herbert Spencer, who brought to his oration the accumulated study and experience of an expert. But there remains Harvey's character as a man, and that is a subject upon which it is good for us to dwell. He lived in an age when men, on account of the state of political and religious feeling, were unusually prone to make enemies, but all that has come down to us regarding his character does infinite credit to the rectitude of his conduct in all the relations of private life. He seemed to be uninfluenced by the strife going on around him, and although attached to the Royalist cause by service and interest he was able to survey the shipwreck of that cause with fortitude and equanimity. His lofty mental stature rendered it impossible for him to stoop to vulgar polemical disputes, and whenever he was obliged to enter the lists in vindication of his scientific views it was always with dignity and forbearance. The real character of Harvey is admirably portrayed by Sir George Ent in his well-known account of his visit to him in his old age, when he found him forgetting the lacerations of the mind in the pure joy of searching and studying out the secrets of nature by experiment. Kings might lose their heads, and old orders might be subverted for a season, but Harvey's gaze was fixed upon the beacon of eternal truth. His devotion to this College was an outstanding feature of his life. As its most distinguished Fellow he had conferred upon it the highest honour, and in a practical manner he exhibited his deep regard by his benefactions. His solicitude for the welfare of this noble library found expression in the erection of a building, a gift of books, and a bequest of money. A few years after his death the whole of the library, with the exception of 140 volumes, was destroyed in the Great Fire, but that disaster proved to be our richest gain, for it produced the great bequest of the Marquess of Dorchester to which we owe the rarity and value of our library. No doubt the liberality of the marquess was in part actuated by the injunction of Harvey to emulate those who had benefited the College, and in our day the bequest of Dr. Lloyd Roberts, second only to that of Lord Dorchester, was surely due to the same spirit. This library, raised up and maintained by the spirit of Harvey, is the noblest monument we possess of that wide intellectual culture with which this College has always been prominently identified.

Harvey, then, in his life and work is the shining example to this College, and the injunctions he has laid upon us in his bequest in 1656 may be followed safely by all who desire its welfare. In these modern days, when we stand at the threshold of momentous changes, we may still look for guidance and inspiration from those injunctions, for they aptly express our duty as physicians, as men, and as Fellows of this ancient and honourable College.

An Address

ON

THE PAST, PRESENT, AND FUTURE OF MIDWIFERY.*

BY

B. P. WATSON, M.D., F.R.C.S. EDIN., F.A.C.S.,
PROFESSOR OF MIDWIFERY AND DISEASES OF WOMEN IN THE
UNIVERSITY OF EDINBURGH.

My first words in addressing you as Professor of Midwifery and Diseases of Women in the University of Edinburgh must be to express my appreciation of the great honour which has been conferred upon me by my election to the chair. That honour is the greater by reason of the fame of so many of its former occupants, among whom were the leaders of their day in this particular branch of medicine. In the past Edinburgh has always been in the very van of obstetrical and gynaecological advance. To maintain that position among the medical schools of the old and new worlds is no easy thing. My feeling of pride is, therefore, tempered by a very deep appreciation of the responsibility of my position, and by a realization of the nature of the task which lies before me.

I take up that task with a determination not to spare myself in its accomplishment and with a hope that if I fail it may at least be possible to say of me that I tried. To help me I have the inspiration and training which I received from my former chiefs in Edinburgh, the late Sir Alexander Simpson and Dr. A. H. Frazer and Barbour, to whom I owe so much. I have also the experience gained during the past ten years as professor of obstetrics and gynaecology in the University of Toronto. When I was called there, ten years ago, it was to take from Edinburgh to Canada the methods of teaching and training which had made the Edinburgh school famous throughout the world. While in Canada I never forgot that and the responsibility to my Alma Mater which it involved. And now, in returning to Edinburgh, I feel that I have that same responsibility to the University of Toronto and to Canada in bringing here all the best that I have learned in that large and progressive medical school and in that great and growing dominion.

In these days of rapid advance in all the medical sciences we are sometimes apt to forget what our predecessors did and how much we owe to them for our present-day position. It does good, therefore, every now and then, to look back a little and inform ourselves of their work, and of the difficulties they had to overcome. When we do so we are invariably surprised at the extent of their knowledge and their great foresight.

In this respect there is no more fascinating study than that of the history of the chair of midwifery in this university. I shall only touch upon a few of the more interesting facts, culled largely from the very full account compiled by the late Sir Alexander Simpson, as the result of exhaustive research into old records and manuscripts, and delivered as an inaugural address to his class in the year of the centenary of the university.

From these researches there appears to be no doubt that to Edinburgh belongs the distinction of having the first chair of midwifery. It was instituted on February 9th, 1726. At that time no medical school in Britain or on the Continent had such a professorship. Strasbourg instituted a professorship of midwifery in 1728, but apparently no appointment was made till some years later, while a century elapsed before Paris followed. The Edinburgh appointment was made by the town council, the patrons of the university. Their minute, as quoted by Simpson, is, in part, as follows:

"The Council having considered the petition of Mr. Joseph Gibson, chirurgeon of Edinburgh, with a declaration under the hands of four doctors of medicine, setting forth the usefulness and necessity of instituting a profession of midwifery, as also an extract of an act of the Incorporation of Chirurgeons, showing their approbation of the said petition, and the capacity of Joseph Gibson, one of their members, to teach art and science; they are fully convinced that it is of great use and advantage to institute this profession, and being well acquainted with the ability and capacity of the said Joseph Gibson they were of the opinion that the Council should appoint him to be Professor of Midwifery in this city and privileges, with power to him to profess and teach the said art, in as large an extent as it is taught in any city or place where this profession is already instituted; and that he should be vested with

*An inaugural address to the students of the Faculty of Medicine, University of Edinburgh.

writings. As a teacher in the extra-mural school he gained such popularity that for a generation medical students in Edinburgh did not consider their education complete unless they had attended his summer course. His enthusiasm for his subject was unbounded, and he prosecuted it to his pupils in such a clear and dramatic way that they could not fail to be interested and impressed. This summer our university conferred upon him the honorary degree of Doctor of Laws in recognition of his worth. We all join in wishing him long years in which to enjoy his retirement.

Dr. Barbour's name has an abiding place in obstetrical literature by reason of his work on the anatomy of labour, a work accomplished while he was still a young man. Along with the late Dr. D. Borry Hart he published a textbook of gynaecology which was translated into many languages, went through many editions, and remains a classic. His contributions to periodical literature have been many, and all are distinguished by originality. The men he has trained occupy distinguished positions in the medical schools at home and on the other side of the Atlantic, and only those of us who have had the privilege of working under him know how much we owe directly to him.

The history of the chair of midwifery in Edinburgh is practically an epitome of the whole history of obstetrics during the past two hundred years. We see first of all the effort to train midwives in the appointment of the first professor in 1726; the gradual extension of that teaching and training to medical students by the provision of voluntary classes for them, and the setting apart of wards for their clinical instruction by Professor Young; the recognition of the status of the obstetrician by the election of Professor Alexander Hamilton as a Fellow of the Royal College of Physicians; the admission of Professor James Hamilton to the Medical Faculty of the university, and the institution of compulsory training and examination of students proceeding to a medical degree; the introduction of anaesthesia in midwifery practice by Sir James Simpson; the recognition by him of the nature of puerperal fever, the combating of which was begun by his successor, A. R. Simpson, as the result of the discoveries of Lister; the invention of obstetrical instruments and the perfecting of operative technique by Sir James Simpson and his successors. And all along obstetrics and gynaecology have benefited by discoveries and developments in other departments of medical science—in anatomy, in physiology, in pathology and bacteriology, and in physics. Thanks to the discoveries of Simpson and Lister, technique has been so perfected as to render the performance of even the most severe obstetrical operations almost devoid of risk to life, and the whole field of operative gynaecology has developed.

Yet there remains a high puerperal mortality, both maternal and foetal. Puerperal fever alone takes a toll of from one to three mothers per thousand births. While the mortality from this disease has been enormously reduced in our hospitals, a corresponding reduction has not been achieved in private practice. The conclusion must be that antiseptic and aseptic principles are not followed with the same careful attention in the patient's home as in the hospital. There can scarcely be any doubt that if the principles of antiseptic and aseptic surgery were applied as rigidly in private as in hospital obstetric practice the mortality from puerperal sepsis would practically disappear. A great responsibility attaches to us as teachers, and to you as students and future practitioners, in this matter.

There is still also a huge maternal mortality from haemorrhages, from the toxæmias of pregnancy, and from complications arising during labour. The numbers of stillbirths—in Edinburgh in 1921 the number was as high as 47.8 per 1,000 births—and of prematurely terminated pregnancies mean a great loss of human life. Women in large numbers still suffer from disabilities, causing great suffering and loss of efficiency, as the result of injuries received in the process of childbirth, and neglected at that time.

With all that has been left us by our predecessors we cannot but think that we ought to be doing better. And, given the proper facilities, there is no question but that we can do better.

It has long been recognized that most of the complications arising in pregnancy, in labour, and after labour are preventable. If they are detected early they can be easily cured. In the case of most of them it is only when they have progressed, unrecognized and untreated, that they are dangerous. The progress which midwifery has made in the last twenty

and is destined to make in the next twenty, is along

the lines of preventive medicine. Preventive medicine as applied to obstetrics means ante-natal care during pregnancy, a minimum of interference during labour, the most rigid attention to asepsis, and the earliest possible carrying out of surgical interference when it is required.

Ante-natal care implies a thorough general examination of the patient as early in pregnancy as possible, and a special examination to make sure that she has the physical configuration necessary for a normal labour. It implies a careful watch on the patient at regular intervals throughout the pregnancy, and the immediate institution of appropriate treatment whenever the least departure from normal is detected.

Unfortunately it is difficult to get women to realize the importance of this careful watching, with the result that the doctor is often only called in when it is too late. The public has to be educated, and it is only through you that that education can be carried on, and you yourselves must first be taught.

We in Edinburgh must not lag behind in this work, for here in our medical school we have the man who foresaw all this present-day development many years ago. I refer to Dr. J. W. Ballantyne. Thirty years ago he was already greatly interested in and an authority on pathological conditions of the foetus. In 1901 he published a paper entitled "A plea for a pro-maternity hospital," and probably largely as a result of that paper a pro-maternity bed, known as the "Hamilton Bed," was endowed in the Royal Maternity Hospital. This was probably the first specific provision for ante-natal care of patients in any hospital. In 1915 Dr. Ballantyne established and has since conducted the ante-natal clinic attached to the hospital.

It is now universally recognized that a pro-maternity or ante-natal department is a most essential—I should say the most essential—part of a maternity hospital. In addition to the outdoor clinic there must be an adequate number of beds for women suffering from the various complications of pregnancy. A hospital which provides only for the women actually in labour, or already delivered, is falling far short of the best that it can do. In the obstetrical department of the Toronto General Hospital, of which I had charge, patients at all stages of pregnancy were admitted whenever their condition required it. Our ante-natal clinic was established there in 1913, and I have always felt that that was the most satisfactory part of my work.

The results of it were shown in the absolute prevention of eclampsia in the patients attending it, the early detection of pelvic deformities and their appropriate treatment, the early treatment, and in most cases cure, of the toxic vomiting of pregnancy, and in other ways too numerous to mention here. What we did in hospital we did also in private practice. We found no difficulty in getting our patients to come to see us early in pregnancy and at frequent intervals throughout. There is nothing that so lightens the burden of obstetric practice as this knowing of the patient beforehand, and there is nothing that is so comforting and reassuring to the patient, as she approaches her time of trial, as the assurance already given her that everything is proceeding perfectly normally.

The problem which faces us is to convince women generally of the necessity for ante-natal care. This, as I have said before, can only be done by the efforts and example of the whole body of medical practitioners. An isolated ante-natal clinic here and there will benefit the community which it serves, and public opinion will be educated to a certain extent, but it will not be until the consulting room of every practitioner is an ante-natal clinic for his district that the maximum of benefit will be obtained.

Along with ante-natal care must go post-natal care; in addition to ante-natal clinics we must have post-natal clinics. As the ante-natal clinic is the great means of prevention of obstetrical complications so the post-natal clinic is the means of prevention of many gynaecological conditions. Post-natal care is preventive gynaecology. No patient should leave a maternity hospital, or be discharged by us as a private patient, until we are satisfied that she has suffered no physical disability as the result of her labour. We can give no such guarantee at the end of ten days or two weeks—the usual duration of her stay in hospital. The ideal we must aim at—and we must always be aiming at ideals—is to get every patient to return for examination four weeks after childbirth. That examination should be made at the patient's home, in the doctor's consulting room, in the post-natal clinic of the maternity hospital, or in the child welfare centre, to every

one of which I should like to see an obstetrician attached for the purpose.

Here again it is a matter of educating the public. That it is worth while attempting is shown by the numbers of women wards suffering from distressing obstetrical injuries. Had they been recognized at the time they could easily have been rectified. Neglected as so many of them are, they necessitate severe and often hazardous operations.

These phases in the development of obstetrics come at a time when in this country a great part of midwifery practice is in danger of passing out of the hands of the medical profession into the hands of certified midwives, and it looks as if the great fight which our predecessors made to give to the women of Scotland the benefit of skilled attention from properly trained doctors were to be in vain. It must be remembered that England was much behind Scotland in this regard, and it almost looks as if we, as the result of legislation common to both countries passed in the last few years, were making a retrograde step. I grant that the training these midwives receive and the work which they do is good, but very often that training is received at the expense of that of the medical student, and the work of the midwives, especially in this all-important branch of ante-natal care, is limited by their having no general medical education.

If we in Britain are to keep abreast of what our cousins overseas are doing we must be prepared to give a much more thorough and intensive training in midwifery to our medical students. Such training cannot be given by making the attendance on a certain number of cases at the patient's home the chief feature. Clinical medicine and clinical surgery could never be taught in that way, and clinical obstetrics certainly cannot. Clinical medicine and clinical surgery cannot be taught by a few isolated clinics given at intervals throughout the session; neither can clinical obstetrics. What is necessary is intensive training. A certain part of the medical course must be set apart for clinical obstetrics and gynaecology, so that the student may concentrate upon them—live, as it were, in the atmosphere of them. During that time he ought to see all the work of the maternity hospital, the ante-natal clinic, the technique in the labour room, the care of the newly born child, the after-care of the mother, and the post-natal clinic.

I have already had experience of this system of intensive clinical training, which I inaugurated in Toronto eight years ago, and I can speak for its efficiency. The objection that the intensive system leads to too rapid presentation of the subject for its thorough assimilation is got over by a continuation of regular clinical lectures to the whole class, say once a week, throughout the last year of the medical course. That also was a feature of our teaching in Toronto.

With such a system it is possible to make the maximum use of all the clinical material available, which under other conditions is largely wasted so far as teaching is concerned. I hope that it may be possible, with the co-operation of my colleagues in my own and in the other clinical subjects, to inaugurate some such system here in the near future. It is simply a matter of arranging the time-table, for I know that they are in accord with me as regards the principle and had arrived at the same conclusions some time ago. The clinical material is here in Edinburgh if we can only use it, and I hope the time may not be far distant when it will be unnecessary for any of you to seek your clinical instruction in midwifery elsewhere.

The Royal Maternity Hospital and the university now work in the closest co-operation for the treatment of the patient and the training of the student. One of the urgent needs at the present time is the enlarging of that hospital and the adapting of it to modern requirements. Our hospital ought to be a place where the future practitioners of midwifery can see obstetrical work conducted in a manner as near the ideal as human effort can make it. It ought to be fitted up to provide all the things which I have mentioned—the ante-natal clinic, ante-natal beds, and with operating and labour rooms, where perfect aseptic midwifery can be carried out.

There is no more urgent need at the present time than funds for the carrying out of this extension and enlargement of the Royal Maternity Hospital of Edinburgh. Until we get it we cannot do all that we ought to for the training of our future practitioners. We cannot be anything but embarrassed when we have to show to our colleagues from distant lands, who visit this city and university so famous in the history of midwifery, a hospital which, though erected

to the memory of Sir James Young Simpson, is many years behind the times.

I can conceive of no more fitting memorial to the fallen, none which would do more to compensate for the enormous loss of Scottish life in the late war, than the erection and equipment of a modern maternity hospital in Edinburgh.

Some Observations

ON

THE BACTERIOLOGY AND VACCINE TREATMENT OF CHRONIC BRONCHITIS;

BASED ON 300 CASES, WITH SPECIAL REFERENCE TO ASSOCIATED NASAL INFECTIONS.

BY

LEONARD MACKEY, M.D., M.R.C.P.,

PHYSICIAN TO OUT-PATIENTS, QUEEN'S HOSPITAL, BIRMINGHAM.

The description "chronic bronchitis" does not convey quite accurately the condition which forms the subject of this paper, for the cases with which it deals fall into three groups which differ both in their severity and in their response to treatment.

1. Those who suffer from frequently recurring attacks of bronchitis but have an interval of several weeks' freedom between each attack.
2. Those who suffer from bronchitis throughout the cold months and are liable to acute exacerbations, but are comparatively free from cough or expectoration during the warmer months.
3. Those who are never free from bronchitis, but are worse during the winter, and are liable to acute exacerbations at any time.

All are liable at some stage to develop asthma as a complication of the bronchitis.

Nearly all such patients find our climate a great handicap, and they would benefit by residence in a warmer and drier land, but very few can afford such a change even during the winter months. It is no secret that ordinary medicinal treatment is disappointing, both to such patients and to their doctors; as time goes on the bronchitis gets worse, and eventually changes in the bronchial tubes, lungs, and heart render the patients incurable invalids.

In the hope of bringing relief to such sufferers I wish to point out a way in which treatment by autogenous vaccines can be made more successful than it has been hitherto. It has generally been taken for granted that in such cases the autogenous vaccine must be prepared from the sputum, and sometimes this can be done with great success. But the practitioner knows little of the technical difficulties which the bacteriologist encounters in attempting to secure pure cultures of the causal organisms in a particular case. It may be easy enough to see the germs but impossible to grow what is seen. The particular sample of sputum may not contain the germs responsible for the catarrh, or may contain one variety only out of several which are responsible. In the most favourable circumstances it is rarely possible to obtain primary cultures in sufficient purity and quantity to make a vaccine, yet most of us feel that there is a virtue in primary cultures that is lacking in the succeeding generations of subcultures.

Then there are the difficulties we make for ourselves. The bacteriologist may not see the patient for whom he is working, he may not even hear the result of the treatment by the vaccines which he has prepared, and so has little opportunity of learning that some of the catarrhal germs are of fundamental importance and others of no account. Better to refuse to make a vaccine than to prepare one from germs which have no pathogenicity.

The impression still seems to obtain that a pot of sputum sent through the post, perhaps twenty-four hours old by the time it reaches the bacteriologist, is suitable material from which to prepare a vaccine. Such a sample is quite suitable to examine for tubercle bacilli, but certainly not for making cultures from which to prepare a vaccine. Such a sample is dangerous because it is fallacious—some of its germs have increased in numbers, other varieties have died. From such a specimen one may prepare an excellent vaccine, but it is largely a matter of chance.

When we also consider the possibilities of error in bacteriological technique, in deciding which germs to include in the

vaccine and which to omit, in adjusting the strength of the vaccine to the age, weight, and condition of the patient, we ought not to be surprised that a considerable proportion of cases so treated fail to make a successful response. Yet I become more and more convinced that if the vaccine is made of the right stuff no case of catarrhal bronchitis will fail to get some relief from it.

Whenever there is sputum to be had it should be carefully examined, but first it must be carefully collected. The patient should be instructed to wash his mouth and throat thoroughly with warm water on waking in the morning, and when next he coughs to expectorate into a short, wide, sterilized glass tube, which is then securely corked. If this first phlegm is partly greenish or yellow there is no need for the patient to collect any more; but if it is simply clear mucus he should try again, for a little purulent material is of great value. This sample of sputum should be sent at once to the laboratory by a messenger who will carry it next to his body or in his trousers pocket, and so keep it warm. Never more than three or four hours should elapse between the coughing of the phlegm and the preparation of cultures; this is so important that it is well worth while hiring a car to save time if a considerable distance separates the patient from the bacteriologist. Such a sample should be examined microscopically; particles should be chosen and cultured on blood-agar, and if the bacteriologist, guided by the microscopic appearance of the sputum and by the clinical symptoms, grows germs which seem adequate to account for the bronchitis, he can hopefully continue his preparation of a vaccine. If, on the other hand, he is not satisfied he should try again with another specimen of sputum. Every sputum is worth examining for tubercle bacilli, for occasionally they are found when least suspected.

Opinions may differ as to the relative importance of the germs found in the sputum in chronic bronchitis, and I will speak only from my own experience. In 130 cases I found germs in the sputum which seemed to me of sufficient importance to be incorporated in a vaccine, though not in all those cases was I content to rely on the sputum alone. The germs so used and the number of cases in which the various organisms were found were as follows:

Pneumococcus	53=40.0 per cent.
M. catarrhalis	42=32.5 "
B. influenzae	58=44.0 "
Friedländer's bacillus	10= 8.0 "
Streptococcus mucosus	8= 6.0 "
Other streptococci	28=21.0 "
Staphylococcus aureus	1= 0.8 "

It will be seen from the numbers that in about half the cases the infection was a mixed one. The list gives a fair idea of the sort of infections encountered in these cases.

Streptococci (apart from *S. mucosus*) are nearly always present in sputum, and are usually of no account; but they are sometimes of real importance, especially when oral or tonsillar sepsis has been a factor in establishing the bronchitis.

The striking successes occur mainly with pneumococcus, influenza bacillus, Friedländer's bacillus, and *S. mucosus*. The *M. catarrhalis* appears in several forms, of which the commonest seem to play an unimportant part in the causation of bronchitis, but the type which grows in soft colonies and is haemophilic is always worth using in a vaccine. I am quite sure that the bacteriologist who does not grow pneumococci and influenza bacilli in a good proportion of his cases of bronchitis is guilty of some technical fault and will not get really good results from his vaccines.

The diphtheroid bacilli (*B. septus*, etc.) are frequently present, but I have never been convinced that they are of importance, and therefore do not use them as vaccines. There are several types of Gram-positive diplococci or diplostreptococci which are as common in the sputum as in the saliva, and might be mistaken for pneumococci under the microscope, but in culture they can deceive only the inexperienced. I know nothing about filter passers and ultramicroscopic germs, and can only hope that if the day comes when they are proved to be the real cause of respiratory infections it will also be proved that they find their way into our vaccines along with the germs we now consider important.

There is no need to say more about the preparation of autogenous vaccines from sputum. Its success depends largely on obtaining a fresh warm sample, free from contaminations with mouth organisms and food. In favourable circumstances it may still be necessary to test several specimens from the same patient before one gets satisfactory

cultures. There are occasions, however, on which it is impossible to obtain a suitable specimen of sputum—for example, in:

1. Small children who cannot be taught to expectorate.
2. Adults who have just recovered from "another bad attack" and wish to avoid further attacks, but have no sputum.
3. Patients who have all the signs and symptoms of bronchitis except that they cough up no sputum or only a little clear mucus devoid of useful bacteria.
4. Patients who as the result of bronchitis are left with a most irritating dry cough.
5. Patients who have developed asthma as a direct sequel to repeated attacks of bronchitis.

It was in trying to deal with a case of severe chronic bronchitis in a little girl that I discovered a test which has since proved of the greatest help in nearly all subsequent cases. Finding it impossible to obtain any sputum, I took cultures from her nasal passages, and obtained such a pure and profuse growth of pneumococcus that I was able to prepare a vaccine from the primary cultures. Her doctor carried out the inoculations and reported rapid and complete recovery.

After that I tested the nasal passages in every case, and soon discovered that there is a definite connexion between the infection of the nasal passages and the liability to bronchitis. From an experience of 300 cases of bronchitis dealt with during the past eight years I can state that:

1. In many cases the nose and sputum show exactly the same infection, but the nasal cultures, being purer and more profuse, are usually more suitable for the preparation of vaccines.
2. In other cases the nose and sputum show different infections, yet both are important—for example, the nose shows pneumococcus, the sputum influenza bacillus.
3. In other cases the nose shows a useful infection, while the sputum shows none.
4. During free intervals the patient frequently carries in his nasal passages the infection which causes his bronchitis.
5. In most cases in which there is no sputum a convincing culture can be obtained from the nasal passages.
6. Vaccine treatment becomes much more successful when cultures from the nasal passages are used, combined, when necessary, with those from the sputum.
7. There is bacteriological and clinical evidence that bronchitis is not a primary disease but an extension or result of a nasal infection. As a rule such patients do not complain of nasal catarrh, though it is not unusual to see mucus coming from the back of the nose into the pharynx.

The following are some of the nasal findings from cases of bronchitis. To those who believe that normal healthy nasal passages abound in pathogenic germs these findings will make no appeal. In my own experience profuse cultures of the chief catarrhal germs are rarely obtainable from healthy persons, and I beg that clinical bacteriologists will give the nasal test a fair trial before condemning it.

The nose was tested in 276 cases of bronchitis and was negative in 20. The 256 positive cases showed:

Pneumococcus	in 118
M. catarrhalis	" 82
B. influenzae	" 49
Friedländer's bacillus	" 38
S. mucosus	" 20
Other streptococci	" 29
Staphylococcus aureus	" 15
Other organisms	" 7

In no fewer than 173 cases the vaccine was made from the nose alone, either because the sputum was negative or because there was none to be had. The bacteria found and so used were:

Pneumococcus	in 73
M. catarrhalis	" 60
B. influenzae	" 30
Friedländer's bacillus	" 22
S. mucosus	" 14
Other streptococci	" 18
Staphylococcus aureus	" 11
Other organisms	" 7

Note the similarity between this list and that of the germs found in the sputum of 130 cases.

On the whole these vaccines were so successful that I am forced to the conclusion that the cause of bronchitis, and also of some types of asthma, is to be traced to an infected state of some part of the nasal passages.

The method which I use for testing the nasal passages is very simple:

1. Plates of blood-agar are prepared and warmed in the incubator.
2. The patient sits with head upright facing the light.
3. A tiny sterile swab of cotton-wool mounted on thin wire is gently introduced into one nasal passage, passed horizontally

backwards until it reaches the posterior wall of the nasopharynx, and withdrawn after being left there for a few seconds. The other side is swabbed in the same way.

4. Without the slightest delay each swab is carefully rubbed on a warm blood-agar plate, which is placed in the incubator.

Let it be made perfectly clear that this test can only be performed with the patient near the incubator; if it is not done in this way it ceases to be the test on which this paper is based.

It happens sometimes that the patient is not well enough to come to the laboratory, and in that case the incubator and media must go to the patient. For this purpose Messrs. Chas. Hearson and Co., Ltd., of Regent Street, London, have made me a little warm box just large enough to hold a few Petri dishes. Its water-jacket can be filled with warm water at the patient's house and will remain at about body temperature for several hours, long enough to get the cultures safely to the laboratory.

Bacteria such as pneumococci and influenza bacilli will usually live for some hours in warm sputum, but they are likely to die on a tiny swab even if it is kept warm; hence the advisability of making cultures immediately. Such cultures often show such a profuse growth of pneumococci, influenza bacilli, Friedländer's bacillus, or *S. mucosus* that a vaccine can be made immediately; but in small numbers any of the above germs are worth subculturing and using.

Diphtheroid bacilli are very common in the nose; rightly or wrongly, I have never attached any importance to them nor used them in a vaccine. I have also ignored small growths of *M. catarrhalis*, streptococci, and staphylococci, but profuse pure growths are of some importance and should be used.

It is instructive to compare the result of cultural examination of the sputum with that of the nasal passages in 128 cases in which both examinations were made.

Table showing Percentage of Various Organisms found on Cultural Examination of Sputum and the Nasal Passages of 128 Cases.

	In the Sputum.	In the Nose.
Pneumococcus ...	30.0	47.0
<i>M. catarrhalis</i> ...	27.5	23.5
<i>B. influenzae</i> ...	34.0	20.0
Friedländer's bacillus ...	7.0	15.0
<i>S. mucosus</i> ...	4.7	6.25
Streptococcus ...	17.0	10.0
Staphylococcus aureus ...	1.0	4.0

Surely these findings show an extraordinary similarity between the bacteriological state of the bronchi and the nose; one is forced to one of three conclusions—either that these catarrhal germs have nothing to do with bronchitis (in which case we must explain the good effects of vaccines by assuming the presence therein of something more than the known catarrhal germs), or that the nasal passages are infected from the bronchial tubes, or the bronchial tubes from the nasal passages.

I do not hesitate to believe that the last explanation is the correct one, seeing that it is an everyday occurrence for a cold in the head to spread to the chest, that nasal cultures are purer and more profuse than those from the sputum, and that the nasal infection persists during the intervals of freedom from any signs of bronchial infection.

All the patients upon whose cases this paper is founded have been sent to me by their doctors, who have given the inoculations and reported their effect.

I have not made vaccines for patients when I found the bronchitis to be associated with advanced renal and cardiac disease, tuberculosis, or mediastinal tumours. Examples of bronchiectasis are not included in this paper.

The aim of the treatment is to cure those who suffer from frequent attacks but are free during the intervals, to relieve cough and asthma and reduce expectoration in those cases in which a cure is obviously impossible, and to improve the general health and reduce the liability to and severity of acute exacerbations in all.

The vaccines are sterilized by heat, their strength estimated chiefly by the amount of culture used and checked by a count of a stained film. Fifteen doses are prepared and given at intervals of a week, starting with a small dose but increasing steadily as long as the patient gets no unpleasant reaction. Such a course appears to confer a definite immunity lasting a year or more in the case of those who continue to be carriers, and for an indefinite period in the case of those who cease to be infected.

A vaccine does not succeed because it rids the patient of his germs, but because it renders him unassailable for a

certain period; during this time his symptoms may clear up completely though he may continue to harbour his germs in undiminished numbers.

Conclusions.

Recurrent and chronic bronchitis can be cured or relieved by treatment with autogenous vaccines.

When sputum is available it should be sent immediately by messenger to the bacteriologist, and not allowed to get cold.

From such a sample it may be possible to make a good vaccine.

Patients suffering from bronchitis usually have an infection of the nasal passages, which is largely responsible for the bronchitis.

Cultures made from these nasal passages according to the method described in this paper show the same sort of germs as are found in the sputum and make better vaccines.

Nasal cultures should be made in every case of bronchitis in which a vaccine is required, and cultures should be made from the sputum also when it is obtainable; in this way one gets a true picture of the underlying bacterial infections and can prepare a more efficient vaccine than if sputum alone is used.

When no sputum is obtainable a successful vaccine may be made from the nasal cultures alone.

Vaccines do not effect a permanent cure, except in those who cease to carry their nasal infection. But in carriers they confer a useful period of immunity.

It is probable that in many instances a rhinologist could throw light on the real nature of these associated nasal infections and suggest some useful local treatment. In the majority of cases the persons so infected are not conscious of any nasal catarrh, though a post-nasal discharge is often obvious to the physician.

The 300 cases upon which this paper is built were just ordinary private patients sent by their doctor to consult me; there was no preconceived plan or idea in the investigations, which extend over eight years, and any merit these observations possess is due entirely to the painstaking work of my two bacteriological assistants.

SURGERY ON THE HIGH SEAS.

BY

A. E. CRABBE, L.R.C.S., L.R.C.P.,

AND

L. R. BROSTER, O.B.E., M.A., D.M., M.Ch.Oxon., F.R.C.S.,

ASSISTANT SURGEON, QUEEN'S HOSPITAL FOR CHILDREN;
SURGICAL REGISTRAR, CHAMBER CROSS HOSPITAL.

The following is a short account of an operation performed on board ship.

The patient, a pantryman of the ship's crew, an old and seedy-looking man of 70, reported sick with retention of urine. At the age of 25 he had contracted gonorrhoea, and showed a healed chancre on the glans penis. For nine months previously he had been troubled with frequent and difficult micturition. There had never been any pain or hæmaturia, but for the last three months there had been constant dribbling.

He was pale, anæmic, and very wasted. His vessels were very thick and atheromatous, the liver was small, the superficial abdominal veins dilated, and the tongue was furred and dry; he complained of headache. There was no tenderness over the kidneys, but the bladder reached up to his umbilicus. The urine was pale, specific gravity 1024, acid; it contained no blood, but showed a slight haze of albumin, and had a somewhat fishy odour, suggestive of *B. coli* infection of the urinary tract. For three days previously he had vomited at night. On rectal examination the prostate was found to be irregular and definitely enlarged, more so on the right side. It was hard but not fixed.

For ten days his condition was relieved by the passage of a silver prostatic catheter. There was always difficulty in passing the instrument through the membranous and prostatic portions of the urethra. It would stick and then suddenly plunge into the bladder with a corkscrew-like action, but no sense of grating was ever detected. Finally one morning it was impossible to pass the catheter, and suprapubic cystostomy was performed.

The operating theatre was a double-bunked sick bay right over the propeller. It was a rough windy day. The stern rolled and pitched vertically up and down, and to this was added a lateral vibratory movement when the propeller came up into surface water. An electric hand torch proved very useful, as the light was out off by the fixed banks overhead. The patient being considered too bad for a general anaesthetic, stovaine-billon was successfully injected intrathecally. No rubber tubing being available, a 1½ in. bore hose-piping, sterilized and stitched into the bladder, proved an efficient if not too liberal means of drainage. An improvised Hamilton Irving receiver was made out of an inverted soap dish.

All the holes were plugged with cork except one in which a thin rubber tube was inserted to siphon off the urine.

The patient stood the operation well, but died two days later, within sight of land.

A modified *post-mortem* examination was performed. The aorta showed very marked atheroma, the lumen being almost obliterated. The liver was small and adherent to the anterior abdominal wall. The left kidney was small and tough, most of its substance being flattened by a large hydronephrotic sac. The right kidney was larger, with a lesser degree of hydronephrosis than the left. The bladder wall was thick and trabeculated. The prostate consisted of a mass of small stones embedded in tough fibrous tissue with practically no gland substance present.

As a sequel to the *post-mortem* examination, which of necessity was performed without gloves, the operator pricked himself in sewing up the wound. No local reaction asserted itself, but within twenty-four hours he experienced "shivery muscular pains," which were followed by a rise of temperature to 103°, and profuse sweating, on three successive evenings, and then the passage of pus in the urine. The latter showed *Bacillus coli* on bacteriological examination.

DISCUSSION ON SOME SIMILARITIES AND DISSIMILARITIES BETWEEN PLANT AND ANIMAL DISEASES,

WITH SPECIAL REFERENCE TO IMMUNITY AND
VIRUS DISEASES.

OPENING PAPER

BY

V. H. BLACKMAN, Sc.D., F.R.S.,

Professor of Plant Physiology and Pathology, Imperial College of
Science and Technology, London.

In common with the study of the human diseases due to foreign organisms, the study of the parasitic diseases of plants has made very great strides during the last few decades. The question, then, naturally arises as to how far the discoveries made in one of these fields are of service in the other—that is, as to how far comparative pathology of animals and plants is a help in future work. On the animal side the greatest advances have been in two fields—those of the exact determination and characterization of the causal organism, and of the physiological study of the basis of immunity. From the last has arisen the vaccine and serum therapy which are the most striking triumphs of modern animal bacteriology. On the vegetable side also very great advances have been made in the study of the etiology of disease, and a very large number of parasitic fungi and bacteria have been described. In the field of disease resistance, however, the advance on the vegetable side no longer runs parallel with that of the animal. Our knowledge of the physiological basis of the resistance to disease of plants is still very rudimentary, and our methods of disease control have been directed mainly to the prevention of the entry of the foreign organism into the host plant, rather than to the destruction by a reaction of the plant body of the organism after invasion.

One of the difficulties that face the plant pathologist in any attempt at broad generalizations concerning parasitic diseases is the very great range in the degree of closeness of association between host and parasite. In the case of most bacterial diseases of man the parasite is definitely internal and produces a marked physiological reaction. In the case of fungal diseases of plants, however, we find very various degrees of closeness of association between parasite and host.

We have the simplest cases where the fungus lives solely on the surface of the leaves, sending down no sucking organs into the host tissues and absorbing no nourishment directly from the host. The injury done is purely mechanical by blocking the stomata and intercepting the light which the leaf requires for its proper activity. Again, we have parasites which live mainly on the surface of the host, yet send down minute absorbing organs into the tissues below. Then there are parasites which confine themselves to the intercellular spaces of the plant, living between and outside the cells and obtaining their nourishment by the diffusion of nutritive substances from the host cells with which they are in contact. A closer degree of association is also to be found in which the main body of the parasite, as in the case just described, lies inside the plant body, in the intercellular spaces outside the cells, but special absorbing organs are present which penetrate the host cells and absorb nourishment from them. Finally, we have parasites like those of wart disease of potato, and finger-and-toe disease of cabbages, which live entirely within the host cells. The degree of structural association of host and plant parasite is thus seen to exhibit a wide range of complexity. The angle from which the plant pathologist can obtain the most illuminating view of the problems which confront him is, however, not the structural but the physiological. The plant pathologist, like the animal pathologist, is mainly concerned with the effect of the parasite on the function of the host—that is, with the interrelation of the physiological processes of the host and the parasite. Disease is abnormal physiology, and its further analysis lies in an adequate knowledge of the physiological processes of the foreign organism and of the plant on which it is parasitic. Just as we find various degrees of closeness of anatomical association, so we find various degrees of physiological relationship.

The different physiological classes exhibiting these various degrees of association are numerous and merge insensibly into one another. At one extreme we have the well-known parasitoid *Botrytis cinerea* (producing a rot of grapes and numerous other plants), where the relations of host and parasite are comparatively simple and well understood. *B. cinerea* is a very common fungus and is able to live as a saprophyte on dead material as well as parasitically. A tissue attacked by the organism is rapidly killed and reduced to the condition of a soft mush. A closer examination shows that the death of the host cells occurs at some distance in front of the advancing threads (hyphae) of the fungus. This action at a distance is brought about by the diffusion from the fungal threads of a powerful enzyme which dissolves the interstitial substance between the cells and brings about their separation and death. This enzyme can be extracted from an active culture of the parasite when grown on artificial media, and its injection into the host plant will bring about all the phenomena of disintegration and death associated with the attack of the living fungus. There is one marked difference, however: the spores of the fungus, when placed under proper conditions on the outside of the leaf of an appropriate plant, can enter and bring about the disintegration of the tissue. An extract containing the enzyme has, however, no action when placed on the surface of the leaf or stem; it is necessary to inject it into the intercellular spaces before it can exert any destructive action. The difference is due to the protecting layer of cuticle which covers the surface of the aerial parts of the plant. Upon this cuticle the enzyme has no action and it cannot diffuse through it, so that it is only when this layer is passed that the fungus can exert any lethal action.

The cuticular barrier is found to play a very important part in many cases of disease resistance. The germ tubes of a parasitic fungus which infects the cuticle-clad stem or leaf must either force the cuticular barrier directly or turn the barrier by entering the plant through the stomata. We find, then, that the question of penetration through uninjured surfaces plays a larger part in the plant diseases than in animal diseases, where entry through the various body openings is comparatively easy. Whether the fungus chooses the easy course through the stomata or the more difficult passage through the epidermal cells is generally characteristic of the fungus, or at least of a particular stage in its life history.* It has been pointed out above that the enzymes of *B. cinerea* have no action on cuticle, so that the passage of the fungus through the cuticularized epidermis of the host

* Why so many fungi should find their way through the cuticle when entry by the easy part of the stomata is open to them is still an evolutionary puzzle.

would seem somewhat surprising. It has been shown, however, of recent years, that the tip of the germ tube, which is developed from the spore of this fungus, becomes closely adherent to the surface of the host plant, and from this germ tube a narrow infection tube is put out which bores its way by mechanical pressure through the cuticular layers of the wall of the epidermal cell. Once these layers have been pierced the enzymes which diffuse from the advancing infection tube can dissolve the cell wall and kill the cells, and infection is complete. The same method of penetration has been observed in a number of fungi. It is obvious that if the cuticle is thick and resistant the mechanical pressure—exerted by what are doubtless the osmotic forces of the germ tube acting against the forces of adhesion holding the tube to the host surface—may be insufficient to penetrate the cuticle, and the host is then endowed with disease resistance to this particular fungus. In a case of this kind, where the physiological relation between the host and the fungus is of the simplest, there appears to be no host reaction with which the parasite is concerned. If the fungus can enter and the cell wall is of a chemical nature to be acted upon by the enzymes of the fungus, then infection occurs and the tissues are killed.

Standing in comparison with *Botrytis*, at the other extreme of physiological interdependence, we find—to take two examples—such parasites as the “rust” fungi, which do so much damage to cereals, and the organism causing wart disease of potato. In the rust fungi we find the question of entry into the host plant is not of so much importance, for the fungus to a large extent enters through the stomata, the cells being pierced by the threads of the fungus after they have gained the intercellular spaces; the cell walls here perforated are not protected by a cuticle. It is after the cells of the host are penetrated by the absorbing organs (haustoria) of the parasite and infection is established that the most striking difference between the rust fungus and *Botrytis* is established. In attack by the rust fungus not only is there no killing in advance of penetration nor even any apparent injury to the cells actually entered by the fungus, but the cells are stimulated, at least at first, to active growth and development at the same time as the fungus is nourished and multiplies in the tissues. We have thus established an association of host and parasite by which, at least for a time, both of them profit—an association to which the term “symbiosis” is applied. One of the difficulties in analysing the nature of plant parasitism results from the way in which parasitism merges into symbiosis in the case of many of the more highly specialized fungi. In the rust fungus the symbiotic relation is not a permanent one, but passes over into definite parasitism, for the leaf cells which have been entered by the fungus and stimulated to active division are ultimately killed.

In resistance to attack by rust fungi, in which entry is by the stomata, protection by the cuticle can, of course, play no part; in fact, it has been shown that the germ tubes of the rust fungus can enter the tissues of almost any plant, but they can only successfully infect their proper host. The question of the rust resistance of different cereals and their varieties is of great economic importance, and fortunately we have some knowledge of the nature of this rust resistance. It has been shown that if the spores of rust fungi are sown on the leaves of cereals which they do not normally parasitize, the germ tubes developed from the spores enter the stomata as usual and the infection hyphae come in contact with the leaf cells. Instead, however, of contact being followed by penetrations and the normal production of absorbing organs, a very marked reaction is produced in the host cells. They rapidly die without being penetrated, and the fungal hyphae die also and so infection is stayed. Immunity to disease in these cases depends not on any active resistance to attack but on a marked hypersensitiveness of the host cells, so that they are killed by mere contact with the parasite, and no symbiosis is established. There has been some suggestion that we have here a play of toxin and antitoxin, but there is no evidence of this; we find no attack followed by recovery, but both the invader and the attacked cells succumb in the contest. In the present state of our knowledge of cell dynamics we cannot analyse the phenomena further. All that we can say is that in this class of plant disease we have in the one case a harmony between the physiological processes of the parasite and the cells of its normal host—a harmony leading to the symbiotic relationship which is the necessary preliminary to the parasitic relationship—while in the other case there is a disharmony between the physiological processes of the would-be parasite and its host, leading both to the death

of the parasite and of the localized groups of host cells, and thus to escape from disease. The case of resistance to rust attack just described is an interesting example of immunity due to definite localized physiological reaction of the host, but it is widely different from the physiological reactions by means of which immunity is acquired in animals.

Another type of physiological reaction to infection on which immunity to many plant diseases seems to depend is the well-known wound reaction leading to the development of cork. The different varieties of flax, for example, show very varying degrees of resistance to infection by *Fusarium lini*. The difference appears to depend on the fact that the parasite enters the tissues without difficulty, but in the case of the susceptible host plants there is little or no wound reaction, so that the fungus can make almost uninterrupted progress through the tissues; with the variety showing resistance the entry of the parasite is followed by a marked reaction, leading to the production of cork, which surrounds the invader with a barrier of dead and impermeable cells so that it is either completely starved out or else its progress is markedly checked.

The case of *Botrytis*, where the parasite can be left out by anatomical peculiarities (such as a thick cuticle), gives us an example of what may be termed passive immunity in plants, while the two cases mentioned, where resistance depends on some physiological reaction of the plant, may be termed active immunity, though the terms have a different significance from that in which they are used by animal pathologists. All cases of active immunity cannot be explained on the basis of hypersensitiveness or on a definite wound reaction. Other physiological conditions play a large part, but exactly what those conditions are it is at present impossible to say. Higher osmotic pressure of the sap, and hyperacidity or tannin contents of the cell, have been claimed by various workers as the basis of the distinction between resistant and susceptible forms, but such theories are built on very insecure foundations. The differences, as indicated above, would seem to depend on more recondite physiological differences of cell metabolism, which cannot at present be analysed.

It will be seen that the immunity with which the plant pathologist is concerned is of the nature of natural immunity, the physiological basis of which in animals is still very obscure. The acquired immunity resulting from one attack of a disease—the immunity which is so characteristic of many diseases of man, and is the basis of modern serum therapy—is quite unknown in relation to definite plant diseases. This is perhaps the most striking difference between plant and animal pathology. The difference between the animal and the vegetable kingdom is to be correlated with the absence of any general reaction to disease of the plant body as a whole. The plant body is only very slightly integrated, and the various plant organs have a great degree of independence, as is shown by the fact that a new plant can often be “struck” from a shoot, a root, or even a leaf. In agreement with this we find such reactions to infection that occur are markedly localized; each group of attacked cells fights a lone battle in which it is largely independent of the rest of the plant body. It is impossible to say that in such a contest between host and parasite there is no production of toxins and antitoxins, or similar substances, but there is no clear evidence of such production, and even in the case of animals the production of antitoxins and other substances associated with acquired immunity seems to be confined to warm-blooded animals. Even if such substances are produced by plants, the chances of isolating them would seem very meagre, for the infection in the plant generally progresses somewhat slowly, at any given moment only a small group of cells being attacked; and, furthermore, there is no reservoir corresponding to the blood stream of animals from which they could be extracted and studied. This being so, it is certainly unlikely that serum therapy can be applied to combating the diseases of plants. Even if such serums could be prepared, there would be the difficulty of distributing such substances, probably colloidal in nature, throughout the plant in the absence of a circulatory system. Even if such difficulty of the continued embryonic condition of the plant. The plant is continually producing new organs, so that any serum therapy to be effective would have not only to endow the plant body with acquired immunity, but with an immunity which would be transmitted to the newly developing organs. The experience of animal pathologists concerning the inheritance of acquired immunity is certainly unfavourable to any such expectation.

activity unimpaired for slightly over two years. Cultures regularly renewed at Haywards Heath have retained some activity for nine years, though it is not known what their original power was. It is, however, certain that attenuated forms do occur, as is clearly apparent when the method is put upon a commercial basis.

Bernard concluded that mycorrhizal infection was a benign disease. He followed Gallaud in regarding the phenomenon of digestion in an infected cell as phagocytosis; the principle is the same, but the immobility of the phagocyte cell entails certain differences in the mode of action. The peculiar manner of growth of the mycelium in the cells is apparently related to immunity, and Bernard considered it to correspond to agglutination. It should be pointed out, however, that the hailing is also frequently seen in cultures. An interesting point is that when once a hypha has entered a seed no further infection is possible; the seed is vaccinated.

Bernard also showed that the tubers of orchids contained an antibody, which is diffusible, killed by heat at 55° C., and specific. Such is a bare outline of symbiosis as it occurs in orchids. The flowering plant restricts the fungus in its distribution by the properties of its cells, either forbidding entry by chemical means, imposing a special mode of growth on the mycelium, or by causing degeneration. Such symbiosis was regarded by Bernard as representing immunity realized by phagocytosis.

Dr. WILLIAM B. BRIERLEY (Rothamsted Experiment Station) said: As particular aspects of our problem will be discussed by speakers who follow me I shall confine myself to a specific and yet fundamental question which appears to me to stand in need of re-examination. For the first few minutes I shall state platitudes, but this is necessary, for it is a direct corollary of these platitudes that I wish to bring before you. Any condition of plant disease is the *status quo* in a physiological complex; it is a physiological equilibrium in which a static condition is not attained; it is a process and not an entity. The component parts of this process are the host and the parasite. Each of these is itself a physiological complex, being the outcome of a certain specific group of germinal qualities (*genotype*) developing under the moulding influences of environmental factors such as temperature, light, humidity, food, and so forth. Diagrammatically this may be shown as follows:

From such trite considerations as this has developed the concept of disease as being the invasion of a defensive host by an active parasite, a see-saw balance in which there is an inverse relationship between the health and vigour of the host and the incidence and virulence of the disease. It is unnecessary to quote definite formulations of this concept, for it is quite generally accepted, but one may perhaps indicate Adam's *Principles of Pathology*, Kolmer's *Infection Immunity and Specific Therapy*, Zinsser's *Infection and Immunity*, and perhaps more particularly Hurry's *Vicious Circles in Disease*. In phytopathology the growing of vigorous plants as a prophylactic against disease is axiomatic.

The question I would ask you is whether this concept is a true picture of reality. Are vigorous plants more resistant to disease than weakly plants, and is there a constant inverse relationship between vigour of host and incidence of disease? One may weaken plants in many ways; by a deficiency in their nitrogen nutrition and supply of mineral nutrients; by interference with their carbon metabolism, their water and temperature relations; by exposure to toxic agents; by wounding; or, on the other hand, one may experiment with plant tissues of different ages and states of maturity. Much experimental work has been carried out along these lines, and this perhaps more particularly with the rust fungi. It has been almost the invariable experience among these students—and one may instance Sheldon, Ward, and Stakman—that the inverse relationship of host vigour to disease incidence does not hold. A careful study of the evidence shows that conditions that are unfavourable to the development of the host are also unfavourable to the development of the fungus and that inoculation experiments on weakly plants usually fail, whereas those on strong and vigorously growing plants of the same variety usually succeed. The evidence, in fact, often shows a direct relationship and not an inverse relationship. It might be suggested that this is

due to the special physiological conditions obtaining in the almost symbiotic relationship of rust fungus to host and that the rust diseases are a special case. That this is not so is clearly shown when the evidence in other types of disease is examined. It is most frequently found that strongly growing individuals of varieties of potato susceptible to wart diseases show a higher percentage of warted tubers and a greater development of wart on the tubers than do weakly individuals of the same variety growing in the same field. Late blight of potatoes, in my experience, attacks vigorously growing plants more easily and produces greater destruction than it does in sickly plants, and L. R. Jones pointed out many years ago that heavy manuring or growth in highly fertile soil lowers the resistance of potato plants to blight and "rot." The same general direct relationship between host vigour and disease incidence and virulence has been pointed out by Marchal in the case of lettuce blight caused by *Bremia lactucae*, by McCue in the case of tomato plants suffering from leaf blight, by Pelletier in the case of citrus canker, by Fromme and Murray in angular leaf spot of tobacco, by Thomas in the *Septoria* leaf spot of celery, by Levino in crown gall of beet, and by many other workers for still other diseases. I do not, however, want to leave behind my initial platitudes and go to the opposite extreme, formulating the generalization that the more sturdy and vigorous the plant the more liable is it to disease. That is an equally false concept. The standpoint that I wish to adopt is that every kind of disease must be taken on its own merits, and that at present it is quite unsafe to draw any generalizations at all. One of the most striking illustrations of this that I have seen is in the manured plots on Barfield at the Rothamsted Experiment Station.

The conception of the diseased state as it formulates itself to me is not that of one organism struggling for its life against another, but as the co-ordination of the activities of two organisms, and ultimately—a far ultimate I grant—of one series of physico-chemical forces integrating with another series. It is not *A B versus X Y*, but *A B plus X Y*.

Within the limits imposed by the genotype, each complex (host and parasite) is modifiable by alteration in the environmental factors. As I see the evidence, this is not a question of biological adaptability but of the presence or absence of certain definitive and specific factors in the physico-chemical complexes—for example, an alteration in pH value of soil or medium, of water relations, temperature, etc., the presence or absence of some particular chemical compound or element, and so forth. I venture to think that perhaps our greatest line of advance in the solution of problems of immunity, resistance, and susceptibility to disease is to attempt to restate many of our biological concepts in terms of physics and chemistry, and to make a physical, chemical, and biochemical analysis of our conditions.

May I say a few words concerning the general issues raised by Professor Blackman? In my opinion the gulf between the animal and plant kingdoms is so profound, and this particularly in the case of the higher forms whose diseases we, as pathologists, study, that to attempt to make anything more than the most vague and general comparisons is to falsify and to confuse every issue. In its morphology and anatomy, its rigid cellular structure, and in its physiological processes the plant is utterly remote from the animals and man. In the plant there is nothing corresponding with the venous and arterial systems, with the lymphatic system, with the alimentary system, and with the muscular, skeletal, and nervous systems. It is in just these characteristic features that the principal pathological responses of higher animals are seen. To my way of thinking it is not in forced comparisons of total disease complexes or in details of pathological histology and so forth that any value can accrue from the collaboration of animal and plant pathologists. Rather is it in the comparative investigation of the structure, life history, genetics, and physiological qualities of pathogenic organisms and their individual relationships to particular host complexes under standardized conditions that advances will be made; and it is in the comparative study of cell chemistry, the study of those physical, chemical, and biochemical problems which are the bedrock of disease.

Professor S. H. GAIGER (Glasgow) said: One cannot but be struck by the remarkable resemblances which at first sight there seem to be between plant and animal diseases. These resemblances, however, on closer study, become less and less apparent. So long as one confines oneself to the examination of the mere anatomical re-

f parasite to host there are resemblances enough. When we studies the reactions of the host against the parasite the differences become marked. These differences are largely due to the absence in plants of systems actually comparable to the systems of animals. Between human and animal diseases resemblances are everywhere apparent. That is so well known nowadays that there is no need to emphasize the important bearing which each has upon the other. But between the plant economy and the animal economy there is a wide structural and physiological gulf which widens with closer examination, and so it must be with their diseases. There can be, for instance, no such thing in plants as the requirement of immunity through an alimentary canal, and of this immunity becoming a systemic immunity through the possession of a circulatory system. The study of the virus diseases of plants is especially interesting. One bears in mind that the first known virus disease was a disease of plants. Now we find another important discovery that there is a virus disease of plants which is solely insect-transmitted. The fact that insects can play an important rôle in transmitting viruses is especially interesting to the veterinarian because it might possibly explain how mysterious outbreaks of foot-and-mouth disease arise in this country. It may be yet found that virus diseases of animals may be insect-transmitted in addition to other means of transmission.

Dr. J. C. G. LEDINGHAM (Imperial Institute, London) said: Professor Blackman has confined himself to infections by the so-called higher fungi. The physiological interactions of host and fungus in plant life should therefore strictly be compared with those observed in fungal infections in animals. With this proviso I believe that the respective manifestations show a closer parallel than Professor Blackman might perhaps allow. Man and animals generally show an extraordinarily high degree of normal resistance to attack by fungi. The few representative fungal infections of man and animals are essentially dermal and characterized as a rule by great chronicity. They have little invasive power, but progress locally with accompanying solution of tissue very much as if a vascular circulation was not present. Some of these fungi also, especially those associated with various tropical mycoses, seem to attack the local tissues only after they have been weakened by certain gross physical agencies as, for example, chronic maceration. I should think that the study of the minute mechanism of these interactions which is possible in the plant may throw a considerable amount of light on similar interactions in man and animals. As we go down in the animal scale truly fungal infections of grave character appear to become more prominent, though it must be admitted our knowledge of the comparative pathology of the lower vertebrates and the invertebrate world is as yet rudimentary. It is possible, however, that looked for transitions are most likely to be found in this zone. Professor Blackman has not alluded to the economically very important group of bacterial diseases of plants. So far as one may judge from the mere reading of descriptions of bacterial diseases in plants, they would seem to offer an extraordinarily close parallel. Though there is no true circulation, the attacking bacteria appear to exercise a considerable amount of invasive power by means of the fibro-vascular canals of the plant. Also there is a good deal of evidence that insects can act as inoculators of such bacterial diseases. As to the so-called virus diseases, we have, of course, a very close parallel in the Rickettsia group of organisms, which are intimately associated with insect transmitters, and it will be most interesting to follow up the study from the morphological side of these plant viruses in the apophyses which transmit these diseases to plants. The factors determining normal immunity to disease in animals are as yet but little understood, and I agree with Professor Blackman that there is here much common ground for research.

Lieut.-Colonel F. P. MACKIE, J.M.S., said: The relationship between the protozoal diseases of plants and animals is also of much interest. To take the example of the flagellate *Leptomonas davidi* of certain euphorbiaceous plants; this flagellate is similar to, and almost indistinguishable morphologically from, the herpetomonas infection of insects and the allied parasite *Leishmania donovani* of kala-azar. These parasites are found side by side in India, and to those like myself constantly confronted with the problem of kala-azar it would be very interesting if the simpler problem in this plant could throw any light on this disastrous disease in man. The

flagellate infection of the plant appears to produce disease and death in the plants affected, and is believed to be transmitted from the diseased to the healthy by the agency of parasitic insects. I sometimes feel a sense almost of despair in attempting to unravel the infinite complexities of disease in man, and think that it might be better to transfer the whole process of investigation to the simpler problems of the parasitization of the lower forms of plant life.

Dr. J. S. DUNKERLY (Glasgow) said: The parasitic flagellate leptomnads are parasites of the laticiferous system in the Euphorbiaceae, etc., and this system extends through the plant and furnishes an analogy to the animal circulatory system. According to Professor Blackman, in the most resistant races of wheat the host cells are killed by the parasitic hyphae, which in their turn are killed or weakened by some reaction of the host cells. This is a local reaction comparable with those produced in diseases of animals. The cells of the susceptible plants, on the other hand, are said to enter into symbiotic relations with the parasitic hyphae which attach themselves to the host nucleus. There is somewhat similar connexion between the nucleus of coccidian parasite, *Caryotrophus*, and the nucleus of the cell of its host, a polychaete worm. The symbiosis of plant cells in fungal disease may be due to a relationship between the host plant and the fungal cell similar to that which exists between algal and fungal cells in lichens. This would not occur so readily between animal and plant cells, which would be more in the relations merely of host and parasite.

DISCUSSION ON MUTATION OF SPECIES.

OPENING PAPER

BY

WILLIAM B. BRIERLEY, D.Sc., F.L.S.,

Head of the Department of Mycology, Rothamsted Experiment Station Harpenden, Herts.

Much of the controversy waged around the subject of mutation has birth in the question of what kind of change should be regarded as a mutation; and perhaps it may not be out of place to spend a short time considering this.

"HIGHER ORGANISMS."

The recognizable characters (*phenotype*) of organisms are the outcome of interaction between germinal or hereditary potentialities (*genotype*) and external conditions. So far as there is direct evidence it appears that the hereditary potentialities are indissolubly linked with the chromosomes of the nucleus. Each potentiality may be attributed specifically to one or more particular unit factors or genes. The latter appear to be distinct entities, perhaps having definite locations in particular chromosomes. This is no hypothetical Weismannian system of "ids" and "idants" but a thing susceptible of definite proof.²⁶

For our purposes phenotypic changes occurring in organisms may be grouped into two categories—*temporary* changes and *permanent* changes.

Temporary phenotypic changes are due to alterations or differences in environmental conditions and the genotype remains unaltered. In consequence these changes (*modifications*) only continue so long as the causal stimuli are operative, and disappear when the organism or its progeny are returned to the original environment. There should be no question that such changes are not to be regarded as mutations; and modifications are therefore without the scope of our discussion.

The second category comprises those phenotypic changes which are permanent—that is, character changes in organisms which persist throughout subsequent generations even when these develop under conditions in which the original stock retains the primitive phenotype. Such changes are the outcome of an alteration in genotype—that is, a change in the chromosomes of the nucleus. This category of hereditary differences may be subdivided into two groups: alterations may result from *inter-chromosome* changes or from *intra-chromosome* changes.

Inter-chromosome changes are those in which chromosomes, parts of chromosomes, or even single genes, may be distributed or recombined in various ways—such as one might shuffle and reshuffle a pack of cards. These changes fall readily into two groups: *normal* distribution and *abnormal* distribution.

Inter-chromosome distribution of normal type is the result of hybridization processes with or without the so-called "crossing over" of chromosomes and of segregation in the offspring. Now it is generally agreed that no permanent phenotypic change which is brought about in this manner may be regarded as a mutation. The latter is the result of a change in genotypic nature which occurs independently of hybridization and segregation or of "crossing over."

Inter-chromosome distribution of abnormal type is of very varied etiology. It may result from irregularities in the assortment or distribution of nuclei or chromosomes during the reduction or other divisions, from halving, doubling, tripling, and so forth, of the usual number of chromosomes, from the "non-disjunction" of particular chromosomes in the reduction division,⁵ from elimination of nuclei, chromosomes, or chromatin substance during segmentation, from chromosome abnormalities, or from the actual destruction of chromosomes by specific external factors such as x-rays,²⁵ and so forth. There would seem to be evidence that changes in the relative positions of genes within the single chromosome may occur, and those although strictly *intra-chromosome*: changes would need to be classed in the present category. There are some students²² who would see in these aberrant chromosome distributions merely the finer ramifications of the normal segregation processes, but the phenomenon are more usually accepted as events *sui generis*. There is no evidence in such processes of the formation *ab initio et ab intra* of new genes. Changes of this nature may occur in the individuals of what is apparently a pure line; and hereditary phenotypic changes which appear to be causally dependent upon such aberrant inter-chromosome distribution are accepted by perhaps the majority of geneticists as mutations. It is, however, vital for proof of the occurrence of such mutation that all possibility of the parental organisms having hybrid qualities be excluded; and it is being increasingly found that claims which have been made in the past, such as that of de Vries for the evening primrose (*Oenothera lamarckiana*), fail when critically examined from this standpoint in the light of recent knowledge.

The second subgroup of hereditary differences comprises those genotypic alterations resulting from *intra-chromosome* changes. If we again use the analogy of a pack of cards, the likeness is not to rearrangement by shuffling but to an actual transformation of a card of one suit into something different. The change is of chemical or physical nature within the gene itself, analogous perhaps to the changes occurring in the atoms of the radium element. Certain prominent geneticists have urged that the term "mutation" should be confined to such an alteration in the fundamental nature of a genetic factor. To obtain convincing proof of such a chemical or physical change *in situ* is, however, an extremely difficult thing. Certainty of specific purity in the original experimental organism is obviously a *conditio sine qua non*, just as certainty of chemical purity is a *conditio sine qua non* in order to prove the existence of mutability of the elements. There are, however, data from researches on *Drosophila* which, in the present state of our knowledge, are best interpreted as indicating the existence of mutation by changes in the fundamental nature of genes.²⁷

The point I have tried to make in the impressionistic and wholly inadequate outline I have sketched of changes in higher organisms (using this term for the whole gamut of living things from mosses and fruit flies to flowering plants and man) is that mutation is no naïve and simple concept. In modern genetical study there are obviously at least two concepts of mutation based on quite different premises and only having in common a basis of apparently hereditary genotypic change. One concept confuses the issue by not differentiating between abnormal distribution of genes and changes in the fundamental nature of genes; whilst the other differentiates clearly but restricts the concept to a very narrow and, at present, an almost theoretical issue. The former use of the term "mutation" is much as though a chemist were to class together the refining of silver from a lead ore containing silver and an actual transformation of the element lead into the element silver.

To obtain satisfactory proof of the occurrence of mutation, using the term in either sense, it is obviously necessary, first, to be minutely acquainted with the genetical constitutions of the parent and the "mutant" organisms, and this can, in our present state of knowledge, only be elucidated by cross-breeding experiments; secondly, to have knowledge of the chromosome structure of the nucleus; and thirdly, to make free use of Occam's razor.

I have, perhaps, lingered overmuch on this first portion of my subject; but if this discussion is to have any value, and if progress is to be made toward the solving of our problems, it is essential that we get our ideas and criteria very clearly in focus. Let me now examine the question of mutation in micro-organisms from the point of view I have suggested. The three groups of micro-organisms that concern us here are the protozoa, the fungi, and the bacteria.

PROTOZOA.

It was early shown that if one experimented with a number of wild forms, subjecting them to selective influences, hereditarily different strains could be bred out; and for some time this kind of work was accepted as demonstrating the efficacy of selection in producing "mutant" strains. It was, however, gradually realized that the phenomenon were not quite so simple as they seemed, and that the results obtained, far from demonstrating the production *ab initio* of new strains, only showed that selective treatment could isolate different strains pre-existing in an original mixed population.

Johansen's *pure-line* hypothesis was then adopted, and more accurate and controlled work carried out, the experiments being based on cultures derived from single individuals of known genealogy. In practically every reliable case entirely negative results were obtained.

However, within the last five years or so, investigations by Jennings,¹⁶ Banta,² Jollos,²⁰ Hegner,¹⁹ and others, have shown that very rarely permanent hereditary changes do arise in what are apparently pure-line stocks. Are these changes to be regarded as mutations? The answer depends, as we have indicated, upon the etiology of such changes, but, unfortunately, of their genetic causation we are yet singularly ignorant. Many of the subject organisms show the form of sexuality known as conjugation, but no student of the protozoa has yet thrown light on the genetic constitutions of individuals by cross-breeding; and of the genetic details of their chromosome structure we are still ignorant. The only basis for the assumption of initial purity lies in the facts that the experiments are carried out on the progeny of single organisms; that self-fertilization over a number of generations in the original stock gives mathematical presumption of a relatively high percentage of homozygous individuals, of which one has been chosen as the progenitor; that in the experiments reproduction is uniparental; and that in parallel cultures the "mutation" does not occur. Anything more critical than this is at present beyond our reach; but this is not a sufficiently critical basis on which to claim proof of the occurrence of mutation, for the crucial test of genetic analysis by interbreeding is absent.

Furthermore, our ignorance of the relative genetic significance of the micro- and macro-nuclei in protozoa (an amiconucleate *Oxytricha* has been found¹), of the nuclear rearrangements in the normal processes of conjugation, and even more of endomixis, is profound. Recently it has been shown that certain of the genotypic changes in *Arcella* are merely the result of a simple increase or decrease in number of nuclei,^{14 21} whilst Erdmann's work¹⁰ indicates that genotypic changes in *Paramecium* may be due to the formation of new strains by normal recombinations of hereditary units in the process of endomixis. These changes would therefore have no greater genetic value than those occurring during normal segregation processes, and all that has been done in the experiments is to separate out hereditarily diverse strains from a mixed population. It follows that a single individual culture is not necessarily a pure line, an understanding that cuts away the very foundations of previous genetical work on the protozoa. It would thus seem that in the protozoa we cannot yet differentiate between genotype changes due to normal chromosome distribution, which are not mutations; changes due to aberrant chromosome distribution, which are only to be regarded as mutation if this term possesses a vague and indiscriminatory significance; and mutations in the more exact sense, resulting from a change in the fundamental nature of one or more specific hereditary units. Even in saying this we are perhaps going too far, for it implies that the hereditary mechanism in the protozoa is in behaviour and genetic structure comparable with that in higher organisms. It may be so, but there is yet no definite evidence that the protozoal mechanism is susceptible of exact factorial analysis as, for example, is that of *Drosophila*.

What I wish to point out is that mutation (in either sense) may occur in the protozoa, but there is yet not one iota of evidence which compels us to believe that it does. Further, that to equate the concept of mutation as it is commonly

applied in protozoology with the several concepts of mutation accepted in the genetical study of higher organisms is to falsify and to confuse the issues.

FUNGI.

Mutations in fungal species have been described by Schieman,²⁰ Watorman,²¹ Blakeslee,⁴ Thom,²² Burger,⁹ Selonten,¹⁰ Hacıucio,¹² and many other investigators. The procedure by which the new forms have been obtained has been to subject, usually but not always, a single-spore culture or its progeny to various physical or chemical conditions, to observe that rarely some entirely fortuitous change occurs in sporadic portions of the growth, to isolate the new form of organism, and to prove that in occasional instances it breeds true to type. This derivative form apparently differing hereditarily from the parent stock is thereafter referred to as a "mutant."

In no case have cross-breeding experiments between the "mutant" and the parent form been carried out, nor is this possible as yet with many of the organisms concerned; and in no case has a cytological study been made of the "mutants." In brief, we are in every case totally ignorant of the genetic constitutions and chromosome relations of the original and derived forms; and there is no certainty of specific purity in any single one of the initial organisms. We can therefore have no knowledge of whether the new form has arisen by normal processes of nuclear rearrangement, by aberrant chromosome distribution, or by changes in the fundamental nature of specific genes. It would seem, therefore, somewhat premature to use the term "mutation" in mycological studies when all that there is evidence for are apparently hereditary changes of unknown genetic causation.

A few words further may be said concerning the possible etiology of so-called "mutants" in fungi. One of the great lines of progress in mycology during the last two decades has been the demonstration of sexuality *in case* or *in posse* in an ever-increasing number of fungi; and we would indeed be a rash mycologist who would assert that sexuality is completely absent from any single species. We have therefore to take into consideration the probability of heterozygosity in many forms and the possibility of it in all; which implies that a single-spore fungal culture has neither greater nor less genetic value than a single-seed or a single-tuber culture derived from some probably or possibly cross-bred higher plant of unknown genetic constitution. No geneticist would accept the latter as a sound basis for any kind of experimental work unless by long and careful breeding-analysis he could unravel its genetic constitution and obtain progeny homozygous for the particular character he wished to investigate. Such factorial analysis is as yet quite impossible in the fungi.

Furthermore, in perhaps a majority of fungi we are not dealing with organisms having simple uninucleated cells; but, as in the Phycomyces, with individuals each of which consists of a single cell containing innumerable nuclei; or, as in very many Ascomycetes and Fungi Imperfecti, with multicellular individuals each cell of which may contain a very variable number of nuclei; of two adjacent cells in a hypha, one may contain five nuclei and the other seventeen or any other number. The possibilities of normal rearrangement of hereditary units or complete nuclei in such a condition are immense and practically unexplored. The studies of Burgess²³ and Orban²⁴ on sexuality in Phycomyces have, for example, shown the probability, not of a heterozygous condition, but, what is even more startling, of a heterocaryotic condition; and the normal genetic ramifications of the permutations and combinations of hereditary units in such a state leave one's mind almost bemused.

Again, practically all fungi that have been carefully observed show vegetative anastomoses of hyphae. Matsumoto²⁵ has just recorded for *Rhizoctonia solani* a phenomenon that I have frequently observed in *Botrytis cinerea*, and which I have no reason to doubt is present in many other fungi—namely, fusions between the hyphae of different strains. The possibilities of genetic contamination in this process are such as to render certainty of specific purity in any initial subject organism quite out of the question.

Practically all fungal species which have been intensively studied reveal themselves to be a congeries of strains differing from each other in a greater or less degree. Most such strains are admitted by all investigators to be constant, but occasionally a strain is studied which gives rise to forms differing from itself but similar to strains occurring wild nature, and these "new" strains are sometimes found to

be constant. Now, I would suggest that this phenomenon is not one of mutation, but that the "mutating" parent organism is genetically impure, being either heterozygous or heterocaryotic, and that its component genetic forms, or different nuclear or chromosome combinations, may occasionally be segregated out by perfectly normal processes of fungal cell-division and reproduction. Occasionally such segregants arise in conditions which favour their reproduction, and, if we chance to observe them, we call them "mutants." If segregation is complete the new form is homocaryotic or homozygous, and naturally, if isolated, remains constant. If segregation is incomplete, the new form may "revert" to the parental type, or at some later date may again show segregation.

Furthermore, it will be evident that in any fungus which gives rise to multinucleate spores—and a vast number of fungi do this—or even in "heterozygous" fungi with uninucleate spores, a single-spore culture may, after very little growth, have given rise to a mixed population, and that when this culture is exposed to selective influences it is entirely reasonable that certain strains in this population should be favoured to the exclusion of others. If segregation has been complete and selection is sufficiently stringent a single "new" strain, perhaps quite different from the parental culture, will be produced; and, if pure, will remain constant even when returned to the original conditions, for there will be no segregation and no subordinate strain to be reselected. If segregation has been incomplete or selection is insufficiently stringent, then, on the return of the culture to the original conditions, the original parental form may again become dominant. Let me give only one illustration. Of certain strains of *Rhizoctonia solani* Matsumoto²⁵ writes: "Fusion is also observed . . . between P1 and P4." "In no case may the strain P4 be so changed as to resemble the form P1, either by changing the culture media or host plants, while P1 may be easily transformed into P4." Now if this be mutation or evolutionary change, we have to assume as its basis some very strange hereditary mechanism. But is it not surely more simple to assume that in the hyphal fusions, nuclei (the cells of *Rhizoctonia* contain many nuclei) from the homocaryotic line P4 have passed into the cells of P1, and that subsequent growth of the latter has produced genetically impure mycelia? The strain P4 is genetically pure and therefore constant. The strain P1 is genetically impure, and under certain conditions nuclear segregation may occur, and reproductive moieties containing only nuclei of P4 are cut off. These, being favoured by the conditions, rapidly become the dominant strain to the exclusion in the culture of the original strain P1. The moment one has grasped the fact that a single-spore fungal strain may be heterocaryotic, and one has realized that the formation of septa by the ingrowing of a diaphragm unrelated to nuclear division or to the number or condition of the nuclei in a multinucleate fungal cell may, if conditions are favourable, give rise to nuclear segregation, one has the key to "variation" and "mutation" in the fungi, and all the phenomena fall into line.

It must be understood that I do not deny the possibility of mutation, even in the narrow sense, in the fungi (to deny the possibility of anything is unscientific); but it is my considered opinion that no single case has yet been described which satisfies the criteria essential to the proof of mutation; nor, until we know vastly more about the genetic constitution and possibilities of individual fungi, can we hope to satisfy such criteria. Personally I find it much more in keeping with the data of mycology as they present themselves to me to interpret all described cases in the manner I have indicated. This applies even to the instance I have myself put on record.⁷

BACTERIA.

There is a vast amount of bacteriological literature bearing on our subject and references to the more recent investigations may be found in the files of *Bacteriological Abstracts*. The may be found in the files of *Bacteriological Abstracts*. The older literature has been collected together and discussed in the works of Adams,¹ Gurney-Dixon,¹¹ Lönnis,²⁶ and others.

Before entering into any detail, attention may be drawn to certain general issues which are usually overlooked. It has been noted that the genetical concept of mutation is based on the premise of certain types of change in one portion or another of the hereditary mechanism, and that to ascertain whether any apparently hereditary change is a mutation or not we must be able at least to analyse the genetic values of the parent and the "mutant," and confirm this factorial analysis, if possible, by cytological data. Unless we can do

this we are very much in the position of a chemist trying to prove mutation of the elements without being able to analyse chemically his initial or his end materials.

Now, quite briefly, we do not know the genetic constitution of a single micrococcus, nor, in the present state of our technique and knowledge, can we ascertain it; and we have no knowledge whatever of the structure or type of hereditary mechanism in bacteria. That bacterial strains may remain constant for years under the most varied conditions, and passing through a myriad generations, implies an extremely delicate and constant hereditary mechanism, quite comparable in its behaviouristic fixity and nicety to that in higher organisms. Of this mechanism we know nothing, and still discuss whether or not bacteria contain nuclei at all. Until, however, we can evaluate the genetic constitution of bacteria, and until we can learn something of the hereditary mechanism involved, to use the term "mutation" in bacteriological studies, and to equate the concepts in genetical studies of higher organisms with those of bacteriology, is mere obscurantism. The only changes of which there is evidence in bacteria are modifications and apparently hereditary changes of unknown genetic causation.

A further point to be noted is that whereas in genetical studies of higher organisms it is essential that the experimental subject be the *individual* of known genealogy, in bacterial studies the experimental subject has been the *culture* containing myriads of individuals whose genealogical relationships are entirely unknown, save that the total culture may be derived from one or more ancestral cultures, or in the rarest cases from a single individual progenitor. The unit in bacterial researches corresponds not with the *individual* of the geneticist, but with the *formation* of the ecologist, and genealogical relationships in bacteriology are from ecological formation to ecological formation, and not from individual to individual. Yet, in bacteria, as in all higher forms, hereditary changes do not concern ecological units, but have immediate causation and expression within the individual *qua* individual.

Again, a fact of immense importance is that not only do we know extremely little concerning the structure of single bacteria, but that we know even less of the developmental and reproductive phases in the life cycle of individual bacteria. Löhneis²¹ and Hort¹⁵ have been the foremost among the few students who have tried to remedy this defect; and although there is much in the recent volume of Löhneis with which one may not agree, it is undoubtedly the most courageous and the most valuable contribution to this aspect of the subject yet published, and a work demanding the closest attention from all bacteriologists. That bacteria may develop through cyclical phases of far greater complexity than the simple life history still taught in textbooks and naively believed by many workers, surely stands in no further need of substantiation. In fact, until we know vastly more about the physiological and morphological phases of development and the reproductive processes in the life cycle of individual bacteria it is altogether premature to speak of hereditary changes in bacterial type. In the face of this ignorance the assumption that "it seems quite justifiable to consider bacteria as asexual throughout their life history"²² which underlies all researches on bacterial variability is a perfectly gratuitous one. All that can be said is that sexuality has not yet been demonstrated, and considering the difficulties attendant upon such work, and the fact that practically no attention has been given to its demonstration, this is not surprising. A comparative view of the results of bacterial research points straight to the occurrence of some form of genetic impurity in bacterial individuals. If it be not so then the bacteria are a class unique unto themselves.

It will be evident, I think, from what I have said that we are ignorant of nearly all the facts and criteria which are essential to any critical study of bacterial genetics. The literature on bacterial variability is chaotic and full of incompatible and contradictory statements and descriptions of phenomena; but from a broad view the principal issues relating to our problem which seem to emerge may, perhaps, be outlined as follows:

(a) There are a great number of bacterial strains which differ from each other to a greater or lesser degree and often live commensally.

(b) Certain strains may remain constant under either unvarying or changing conditions, whereas certain cultures of other strains may show no variation, whilst parallel

cultures of these strains may show variation to a greater or lesser degree.

(c) The change may apparently take place gradually or suddenly; it may be an apparently permanent change, or it may be that selection appears to be effective in either or both *plus* or *minus* directions; it may be a fortuitous change, or it may apparently be a specific and teleological response to one or more particular operative stimuli.

(d) No experimental research has been carried out by the following of single individuals of known origin through many generations (Hort has come the nearest to this), and only in the rarest cases is any experimental culture to be referred back to a single individual progenitor (and I very fully agree with Hort's adverse criticisms of the isolation methods in *voguel*).

When viewing broadly the chaos of bacterial literature relative to variation I do not think anyone knowing the literature of "genetics" and evolutionary thought prior to about the beginning of the twentieth century can fail to be impressed with their essential similitudes. Identical phenomena are described, similar points of view are adopted, and the same interpretations appear. Genetical students of higher forms relinquished these ideas between the years 1900 and 1910. About the latter date protozoologists began to reach out to a more exact *pure-line* formulation of their problems. Mycologists are just beginning to see the light, but with rare exceptions bacteriologists are still in the darkness of a pre-Mendelian and a pre-Johannsen period.^{23, 24}

If one considers the more theoretical aspects of the published data on bacterial variability there would appear to be only two feasible interpretations:

(a) It may be assumed that the bacteria possess an hereditary mechanism sufficiently delicate to distinguish, for example, between different blood serums or temperatures only separated by one degree, and yet sufficiently static to do this without appreciable variance for innumerable generations; a mechanism which, according to the results of reliable students, must be almost uncannily intelligent, overcoming the specificity of enzymes, to adapt itself to new conditions in a manner quite unequalled by higher organisms, and yet a mechanism which, according to reliable students, must be of the most labile order, in certain cases being apparently at the mercy of almost any chance condition and changeable at will with the greatest ease. As I have indicated, the bacteria would then be a unique class of organisms and any deductions drawn from their behaviour would be quite inapplicable to any other organisms.

(b) On the other hand, we may assume that bacteria possess an hereditary mechanism comparable in all behaviouristic respects (we know nothing about structural aspects) with that of other organisms, and the occurrence, perhaps only at rare intervals, in the bacterial life cycle of some form of cell fusion giving rise to genetic impurity.

Both hypotheses would fit the known data on the behaviour of bacteria. Now without entering into any detail, but bearing in mind our ignorance of the genetical constitutions, hereditary mechanisms, and life cycles of the bacteria, and the fact that the data have been derived from researches in which the unit basis has been the ecological formation and not the individual organism, the second of the above alternatives would seem, to my way of thinking, overwhelmingly the more reasonable. Granting the assumption of the occurrence in bacteria of genetic impurity with some mechanism of segregation, all the data concerning variability and apparent mutation in this group fall astonishingly well into line with modern genetical conceptions. Genetically impure single bacteria might occasionally or frequently give rise to mixed populations, just as genetically impure fungus spores might do, or just as single plants of, for example, *Oenothera lamarckiana* would do, were all their seed and that of their offspring sown for a myriad cross-breeding generations. As has been described for the fungi, selective influences might then change the whole physiological or morphological facies of a bacterium in culture merely by the favouring or isolation of its constituent strains. According to the degree of segregation and the stringency of selection the change would be temporary and susceptible to reverse selection, or permanent.

Perhaps one may be forgiven for showing the manner of this change diagrammatically and reduced to its simplest proportions; but it must be realized that in actuality such changes are probably of an extremely complex order.²⁵ A genetically impure bacterium, A, would, in the vast majority of its progeny, merely reproduce its own condition, A,

but occasionally it might segregate out its constituents in pure form, B and C. Those latter would be present in such infinitesimal proportion as to be totally inappreciable in the culture. If, however, the conditions were so changed as to favour the development of the submerged forms, these might gradually become the dominant forms, as in IIIa and IIIb. If the selection were sufficiently stringent over a large enough number of generations the submerged form A might die out, leaving pure cultures of either B or C, IVb and IVc, according to which of these types had been favoured. An apparently new form would now have been developed, which, as it is genetically pure, will remain constant. If, however, the original impure type A has not been completely eliminated it may again gradually become dominant on the reversal of the selective processes. The longer a genetically impure strain is subjected to the action of selective conditions the purer genetically it will become, and the longer it will take to "revert" when returned to the original conditions. This phenomenon, so simple on a basis of genetic impurity in the individual bacterium, has been a most fruitful source of controversy and speculation in the past,¹¹ and is now being found of "extreme interest" by protozoologists.¹²

In this consideration I have not entered into detailed criticism of the several experimental results, but have kept the treatment broad and comparative, and tried to indicate the relative value of certain genetical concepts in the biological groups that concern us. If our studies are to be of value it is imperative that we have our foundations firm and straight in the solid knowledge of structure and life history of individuals before we investigate variations in superstructure and make positive claims regarding mutation. We must have our criteria precise and cleanly cut.

SUMMARY.

A mutation is not any old change in an organism. In the strict sense it is a change in the fundamental nature of one or more hereditary units; in the wider sense it is a change in genotype due to abnormal distribution of hereditary units. A change originating in normal distribution of hereditary units in crossing, or as a result of redistribution due to the appearance of any form of genetic impurity in the parent individual, is not a mutation.

The proof required to establish biological mutation is no less precise than that required to establish chemical mutation; and like the latter is dependent upon analysis of the original and the derived products.

The concept of mutation held at present by most microbiologists cannot be equated with that held by genetical students of higher forms. It is a more nebulous and inclusive concept, for their subjects have not yet been found susceptible to factorial analysis. Detailed cytological information re the hereditary

in the protozoa and fungi there is the possibility of the origin of apparently new and distinct strains in the normal cytological processes, and it is suggested that apparent mutations may be due to the selective isolation of such strains.

In the bacteria it is suggested that a similar hypothesis is the most feasible on which to interpret present data; and that it will explain the facts of "variation" and "mutation," bringing them into line with genetical concepts.

The possibility of mutation in micro-organisms is not denied; but it is considered that no adequate proof of such mutation has yet been adduced, or can be in the present state of our technique and knowledge. We are trying to write as we have learned our alphabet!

DISCUSSION.

Professor DAVID ELLIS (Royal Technical College, Glasgow) said: It is well known to bacteriologists that the adaptability of bacteria to changed conditions, whether internally or externally excited, is far greater than that possessed by organisms higher up in the scale of evolution. We could, therefore, on a priori grounds expect in the bacteria that capacity for change which has sometimes brought systematists to the verge of despair. Instances of rapid changes in form and function on the part of bacteria are numerous and appear in every aspect of bacterial life. On very slight provocation bacteria change in shape and size, their virulence and their growth in various media are subject to change, as also is their reaction to various stains and their power of fermenting sugars. It is necessary to remember that our test-tube cultures are very artificial, and that it is possible to produce relatively as much change in three months as would take place only after a hundred years, or more in the breeding of some of the higher animals, or plants. The most potent of such external changes is, in my experience, the influence of the mass of excreted matters which the bacteria liberate into the surrounding medium. For instance, when test-tube cultures of the *Coccacoccus* were subcultured at frequent intervals most marked changes were observed. The cells lost their cohesiveness and became reduced from large masses of cells to tetrads, triads, diplococci, and even unicocci. I found this procedure to take place in all of 19 different species of *Sarcina* that were investigated. The change was followed by a gradual development of motility. The final result showed organisms that were so different from the first cultures that they would certainly not, if considered casually, be placed in the same species or even the same genus. All had been brought about by the simple process of removing the cells at the earliest opportunity from their own excretions by frequent subculturing. Every coccus is, therefore, potentially capable

of movement and of existing apart from its fellows as a single cell.

Those functions in the higher plants for which the nucleus is responsible are carried out in the non-nucleate plants and animals by the general body of the cytoplasm. We may therefore assume that the germinal or hereditary characters are located in the lower non-nucleate organisms in ultra-microscopic particles in the cytoplasm. Such particles may be regarded as physical or chemical entities capable of autocatalysis, and as such are to be regarded as possessing a value equal to the potentialities that are lodged in the chromosomes of the higher organisms.

Under certain circumstances *Crenothrix polyspora*, one of the iron bacteria, departs from its normal activities, and lashes itself into a frenzy of reproductive activity. From single threads thousands of minute specks ooze out in zoogloae. These specks do not cease to multiply after leaving the thread. Under ordinary circumstances *Crenothrix polyspora* is a placid organism, and pursues its path in life in a very leisurely fashion. If, however, a particular set of conditions arises it departs suddenly from its habits, and on occasions causes a large sheet of water within a short time to assume a very dirty appearance. The transformation has been effected from a comparatively large thread-like organism to one which is composed of coccus-like specks of living matter which, so far as one can judge, never return to the thread condition.

A somewhat dramatic change may take place in the life history of *Cladothrix dichotoma*, another of the iron bacteria, which lives in water in the form of long threads, each containing a single row of short rods, and which can be cultivated artificially without much trouble. Its method of reproduction is very simple, and consists solely of cell division of exactly the same nature as takes place when the bacillus divides vegetatively. The new rods that are thus formed escape usually from the top, sometimes laterally. It was stated by Zopf many years ago that sometimes spirilla issued laterally from the *Cladothrix* thread. His statement was received with incredulity by the majority of bacteriologists, but on reading over his papers I found Zopf's statements to bear such an impress of the truth that I resolved to repeat the experiment. I may state that for eighteen months I made almost weekly subcultures under open conditions of *Cladothrix*, and at last, after eighteen months, my patience was rewarded, and I observed the complete change that took place in *Cladothrix*, which followed the course described by Zopf. It was that spirilla issued forth from the threads instead of straight rods. These spirilla had polar cilia and were composed each of a few rods, but some were composed of one rod which assumed a spiral form and was propelled by polar cilia. Unfortunately, it was not possible to follow the further development of these spiral rods.

Among the iron bacteria are two very common forms in this country, which are named *Leptothrix ochracea* and *Gallionella ferruginea* respectively; there is a third in the same habitat which I found and named *Spirophyllum ferrugineum*. In my further investigations of these three organisms I found that, except for their outward shape, there was absolutely nothing to distinguish between them. They also practically always occur in association, usually two out of the three, rarely three together. I hold that these are all pleomorphic phases of one and the same organism.

He must be a courageous investigator who sets out to prove mutation for bacteria in such a way as to satisfy the criteria imposed by the geneticists of the higher forms. He is debarred from making deductions from cytological considerations owing to the extreme minuteness of the forms and their rudimentary structure. He cannot undertake factorial analysis by cross-breeding, for no fusion of cells has been observed. It really comes to this, that proof of mutation is obtainable only in the case of cells of plants with a certain measure of differentiation and with sexual reproduction. And yet one feels that the phenomenon of mutation happens in bacterial life just as much as, or probably more so than, in higher organisms.

Dr. F. W. TWENT said: I do not agree with some of the rules laid down by Dr. Brierley. It seems to me that there can be no such thing as genetic purity in biology, certainly nothing comparable to the chemical purity of an element. I also look upon differentiation of morphology as a very crude method of attempting to demonstrate

Dr. J. S. DUNKERLY (Glasgow) said: While agreeing cordially with Dr. Brierley's remarks on the need for strict genetic criteria for distinguishing true mutations, it is possible that we find in protozoa one of the characteristics required by Dr. Brierley's tests—namely, a fundamental change in the nature of the chromosomes. In *Arcella* and other protozoa the chromidia, as distinct from the nucleus, can form secondary nuclei, which carry on the life cycle. Chromidia can even undergo "chromidiogamy," a method of syngamy in which the nuclei take no part whatever. This may produce a fundamental change in the chromosomes, inasmuch as they are formed anew from chromidia, not from the previously existing chromosomes of the nucleus.

Dr. J. C. G. LEDINGHAM (Lister Institute, London) said the speaker claimed that no adequate proof of mutation of bacteria had yet been adduced, nor could be adduced, in the present state of our technique and knowledge. If we accepted Dr. Brierley's definition of a mutation as a change in the gene of a homozygous individual, he was simply stating a truism, as the genetic constitution of bacteria could not be analysed on lines employed, for example, with plants and animals. He had described the literature of bacterial variation as chaotic, and doubtless it was so to one looking at the subject entirely from the genetic point of view; but Dr. Brierley should be aware that an extremely small proportion only of the vast mass of literature on this subject was the result of work directly instituted with a view to inquiry into possible genetic mechanisms. The great mass of the work on that subject had been carried out almost solely with the object of explaining peculiar behaviour and peculiar phenomena in bacterial growth and metabolism; and the contributions of bacteriologists to this field had undoubtedly enriched our science. The few contributions to the purely genetic side (if such existed in bacteria) by Hort, Löhnis, Bergstrand, Mellon, and others were regarded by most bacteriologists as still very much *sub judice*. In any case the evidence of the existence of cycles in bacterial life was as yet too small and flimsy to carry much weight on the general question. The terms "mutation" and "mutant" had doubtless often been used rather loosely by bacteriologists; but, as a rule, they had been taken to connote truly hereditary changes, temporary adaptation to environment being excluded. If mutation was used in the sense of an "hereditary change of unknown genetic constitution" as de Vries used it, it did not seem inappropriate in bacteriology, and until we could talk about genetic constitution in bacteria it seemed justifiable to employ the word "mutant" in this sense. In dealing with a group of organisms such as bacteria, which had not proved susceptible of analysis into organs or genetic elements, it seemed wiser to deal with the phenomena only and to steer clear of genetic hypotheses derived from analogy. Whether these phenomena were due to change in the germ substance of the organism or to suppression of parts of it as had often been suggested, or whether they were due simply to selection of individual constituents of the race, might not be established in all cases, but nevertheless these phenomena were of immense importance, though the exact name for them might be disputed. In his opinion, the single-cell procedure in bacterial work had not advanced matters very much and had taught us little more than the single colony. Finally, if all hereditary changes leading to evolution of species were held, as Dr. Brierley suggested, to be due to primary impurity of strain, the attempt to demonstrate the genetic mechanism of the change was, from the practical point of view, not worth making.

Dr. BRIERLEY, in reply, said: The evidence that has been brought forward by Dr. Ellis regarding pleomorphy and cyclical changes in bacteria is of great interest and all goes to show our almost complete lack of knowledge of the basic facts of bacterial genetics. Much more work of this kind must be carried out before we shall be in a position to understand hereditary changes in bacterial type or to evaluate them in the concepts of the genetics of higher forms. I am, however, entirely opposed to Dr. Ellis when he would make genetical criteria more inexact in order that our vague and partial knowledge of the genetics of micro-organisms may be interpreted. Surely it is not our criteria that must be rendered nebulous and inexact but our knowledge of micro-organisms that must be made less nebulous and more exact. The standpoint of Dr. Ellis in this particular matter seems to me a negation of all scientific methodology.

Dr. Twort comments upon the fact that I insist upon a state of genetic purity as a *conditio sine qua non* in investigations having as their end the elucidation or artificial production of mutation, and asks me, "What is genetic purity?" This is no easy question to answer where micro-organisms are concerned. In higher organisms we can obtain a state of genetic purity or homozygousness by certain definite breeding techniques, a long story into which I cannot enter here. In micro-organisms the application of such techniques is not yet possible, nor have we any method of genetically analysing our organisms or of uncovering recessive factors. We have, therefore, no means of ascertaining whether or not micro-organisms are genetically pure, which is one of the reasons why I find it premature to use the concept of mutation. Dr. Twort also states that morphology is far too coarse a criterion for bacterial mutations, which are of a more subtle character. I fully accept this, but cannot quite see its bearing on our discussion, for physiological powers are the expression of germinal qualities under particular conditions just as are morphological structures.

Dr. Dunkerly has indicated very clearly some of the complexities to be met with when the hereditary processes of such a form as *Areolla* are considered. The point that I have tried to make is that these and similar complexities are always overlooked. It is just the presence of such little understood hereditary mechanisms that makes it premature to equate genetical concepts as between higher organisms and micro organisms. So far as I understand Dr. Ledingham's criticism, it is that evolution can only have come about if mutation has occurred, that we accept the reality of the evolutionary process, and therefore must accept the phenomenon of mutation as a fact. Granted the premisses, this conclusion would be true; but must we accept the premisses? I think not, for there are surely many other modes of evolution than that of mutation. It is a very valuable thing to hear from Sir William Leishman that this evidence, on which much doubt has been cast, may be accepted. It is fundamental work and must go far to revolutionize our concepts in bacteriology.

AN OUTBREAK OF FOOD POISONING BY MILK, CAUSED BY *B. AERTRYCKE*.

BY

W. R. WISEMAN, M.A., M.B., B.Sc., F.R.F.P.S. GLASG.,
Bacteriological Laboratories, Public Health Department, Glasgow.

Owing to the remarkable circumstance that British records contain only ten instances of epidemic food poisoning due to the distribution of cow's milk, and that in only three of these has the causative micro-organism been completely identified, it has been considered of importance to administrative authorities and of interest to bacteriologists to bring forward the facts contained in this communication. I am not concerned with these ten outbreaks except from the bacteriologist's point of view. Notice of one of them was brought before the Royal Academy of Medicine, Ireland, by Dr. O'Kelly in March, 1922.¹ It was due to the *B. enteritidis* Gaertner. The other nine are collated by Dr. W. G. Savage in his recent publication, *Food Poisoning and Food Infections* (1920).² Although in that list of nine the organism is given as completely fixed in three cases and as being *B. enteritidis* Gaertner, I have to note that in one of these three (the Chorley outbreak of 1914) the report of Professor Delépine, which is given in the county medical officer's report,³ describes the causative organism repeatedly as a "bacillus of the *enteritidis* type." Notwithstanding that in the last few words of his report Delépine makes the statement that "the *Bacillus enteritidis* isolated from the ear of the cow was capable," etc, this report does not fix the organism bacteriologically as other than a member of the Gaertner group. I take the number on the list, therefore, as reduced to two. While, then, the specific organism has been fixed on three occasions as *B. enteritidis* Gaertner, the outbreak now under review brings to notice an organism which to our knowledge has not hitherto figured as the cause of an epidemic due to the consumption of cow's milk—namely, *B. aertrycke*.

THE PAISLEY OUTBREAK.

The details of this outbreak admit of quite a short description. On May 8th (a Sunday), 9th, and 10th, 1921, there occurred in Paisley a considerable number of cases of sudden illness characterized by headache, abdominal pain,

vomiting, and diarrhoea, with temperatures, generally low, reaching in some cases to 101° to 102° F. They were investigated by the medical officer of health of the town, Dr. G. V. T. McMichael, and to his courtesy I am indebted for permission to make use of the epidemiological facts which were ascertained. Fifty-two people, whose ages ranged from 14 months to 83 years, were struck down by the outbreak, and these involved eighteen families. A thorough investigation of the various food supplies of the patients was immediately undertaken, and it soon became apparent that the only source of food supply common to them all was a particular dairy which retailed cow's milk. The affected area was very circumscribed and therefore easily handled. In addition to this exclusive fact of common supply the suspicion that fell upon the dairy was heavily supported by certain other facts that emerged. Among these were the following facts:

1. Three patients, a husband, wife, and child, whose ordinary milk supply was from a different source, were supplied by this dairy on Sunday, May 8th; two of them sickened within twenty-four hours and the third within sixty hours. These three people were lodgers in a house occupied by two tenants who did not deal with this dairy and who escaped illness.
2. Four of a certain family (which figures in the bacteriological investigations) receiving this milk were affected, while the fifth member of the family, a child of 5 years, who did not receive milk from this dairy, escaped. This family were ordinarily supplied from another source, but on May 7th and 8th were supplied by this dairy. Three members sickened on May 9th, and one on the 10th.
3. Of a certain family of ten (which also figures in the bacteriological investigations) eight suffered, one escaped, and one was breast-fed. This family received the same milk supply as the family of five just mentioned, while it was ascertained to a nicety that their other food supplies differed *in toto*.
4. There was still another family which was not served by their usual dealer on May 8th but by the dairy in question, and two of its members sickened the following day.
5. The age of some patients was as low as 14 months.

In addition, it has to be stated that five cases of illness where a different milk supply was used came under notice. Three of these were individual members of three households where the other members made no complaint, and two of them were brothers of a girl under treatment at the time for influenza. They are therefore not serious exceptions and do not invalidate the conclusion of the medical officer of health as to the defaulting milk, and they do not exceed in number the apparent exceptions encountered in the majority of such investigations.

In view of all the facts the opinion of the medical officer of health which incriminates the milk supply is conclusive. The mortality in the epidemic was *nil*. All the patients were convalescent in a week.

Source of the Contamination.

It has to be said at once, to the disappointment of administrative officers—a disappointment to which, unfortunately, they are not unused—that the source was not determined. The dairy in question had its supply from two farms, one of which was unexceptionable in every respect, while the other was just the reverse. This second farm had been well known to the medical officer of health of the Barhead district as quite unsatisfactory from a hygienic point of view, and Dr. McMichael's inspection confirmed this opinion. At the same time this inspection, which was carried out in concert with the Paisley veterinary inspector, did not reveal any signs of disease or illness among any of the animals, and the farm people themselves professed to be well, and refused to submit themselves to examination by a bacteriologist. It was said to be a fact that part of the consignments reaching Paisley on these days (May 7th to 9th) was reserved for ice-cream dealers in Barhead and delivered thereto, but that no case of similar illness occurred there. Though grave dissatisfaction attached to the conditions obtaining at this farm, its milk supply was not stopped, and no further case occurred after May 11th.

Bacteriology of the Outbreak.

General Remarks.—It was a rather awkward circumstance that the bacteriologist called upon resided in a different town. He would otherwise have been in contact with the materials sooner than he was—an all-important matter. As it was, the writer received two samples of milk on May 24th, fifteen days after the commencement of the outbreak, probably for the purpose of clearing the farm rather than for detecting the source of contamination. They revealed nothing. With such an elusive organism as *B. aertrycke* one could have no reasonable hope of finding it in these materials after such an

interval. The examination of the patients, however, was satisfactory, and established the cause of the trouble. Materials from four cases were submitted and three of those gave positive results. The incubation period was unknown in the majority of the cases, since their daily milk supply was uninterrupted close up to the time of illness. But there were cases supplied by this dairy only on this week-end. In one such family the latent period was twenty-four hours in two cases and seventy-two hours in one case. In another such family supplied only on May 8th, two members sickened on the 9th at 5.30 p.m. (hours of milk delivery not fixed). In a third family the utmost limit of the latent period in three cases is forty-eight hours, and may in fact be about twenty-four, though in one case it may possibly extend to seventy-two hours. The majority of the known cases show a latent period of twenty-four to forty-eight hours. It is no doubt determined by the amount of contamination ingested.

Character of the Stools.—One specimen, submitted on the fourth day of illness, from which *B. aertrycke* (Mutton type) was isolated, contained much mucus with traces of blood. It was not of a faecal character. A specimen from a second patient, giving a positive result and submitted on the seventeenth day of illness, was fluid and faecal in character, with no mucus. The importance of the character of the stools is great from the point of view of medical officers of health. For on their initial impressions as to whether or not the stools at the beginning of an outbreak are due to dysentery there may hang the very possibility of getting hold of samples of the actual food materials that were consumed.

Experimental Results.—The materials giving positive results were the faeces of two patients and the blood serum of a third; a fourth specimen was submitted on the seventeenth day and was negative. The agglutination reaction of this serum was diagnostic for the Gaertner group of bacilli. It reacted equally with a stock *B. aertrycke* and with the bacillus isolated from the faeces of one of the patients which was subsequently fixed as *B. aertrycke*. It failed to agglutinate *B. enteritidis* Gaertner, and reacted with *B. paratyphosus* B, Schottmüller, only at low dilution, 1 in 25. This was on the eighth day of illness, and during convalescence. The organisms from the two patients satisfied all the morphological and biochemical tests for bacilli of the true Gaertner group. They were highly pathogenic for guinea-pigs, and one of them, *B. "Smith,"* after twelve months' culture on agar, is still able to kill a 600-gram guinea-pig in six days after intraperitoneal injection of 0.1 c.cm. of a twenty-four hours' broth culture. The post-mortem appearance in this last test comprised emaciation, congestion of subcutaneous and intestinal veins, a patch of haemorrhage in the wall of the large bowel, and a spleen enlarged to thrice the normal. The bacillus was recovered from the spleen and heart blood. Since these bacilli were agglutinated in high dilution of a specific serum of *B. paratyphosus* B, and were negative to a *B. enteritidis* Gaertner serum, they were subjected for final differentiation to the absorption test.

The results of the tests show: (1) That one of the organisms, *B. "Smith,"* is identical with the Mutton type of *B. aertrycke*. (2) That the other organism, *B. "Todd,"* is *B. aertrycke*, but is of a different type from *B. "Smith,"* and while not identical with *B. aertrycke* ("N") has a close resemblance to it. It differs from the latter (a) in its uniform agglutinability, (b) in the fact that even after the heaviest absorptions, graduated up to eighteen slants to 1 c.cm. of diluted serum, it is impossible by means of it to absorb the secondary agglutinins for *B. "Smith"* and *B. aertrycke* (Mutton) from the *aertrycke* "N" serum. Only half the latter was taken out, although the primary agglutinins have gone.

A word of explanation is necessary as to what is meant by *B. aertrycke* "N." Towards the end of 1920 I received from the Lister Institute, on request, the two *aertrycke* types, Mutton and Newport. These were the cultures that were set in action in these experiments. When the experiments were well under way, the abnormal behaviour of this "Newport" culture became obvious, for in its agglutinability it differed widely from the Newport bacillus which figured in the work of others. In this communication it is therefore named "N." "N" is undoubtedly a member of the *B. paratyphosus* B food-poisoning group, but no time has yet been available for working out its exact relationship with *B. aertrycke* (Newport) No. 129, National Collection of Type Cultures.

For the purposes of this investigation the "N" bacillus has served well enough, since the primary requirement was a comparison with two known organisms. At the same time, the more normal behaviour of *B. aertrycke* (Newport) No. 129

suggests the possibility that *B. "Todd"* may be identical with it. At the time when the "N" bacillus was received by me the publication of the list of the National Collection of Type Cultures was not yet in existence. Whether or not the "N" bacillus is a new type or a modification of No. 129—I have not yet had the opportunity of determining this—it is interesting and unusual to find two distinct types of *B. aertrycke* figuring in the same epidemic.

SUMMARY.

1. In May, 1921, an outbreak of food poisoning in Paisley struck down 52 persons of ages ranging from 14 months to 83 years, and has been shown to be due to the consumption of cow's milk. The actual source of the contamination was not discovered.

2. Regarding the administrative investigation of such outbreaks, although one of these has been known to occur in which the stools were of a non-dysenteric character, grounds have been adduced for the opinion that it is not wise to neglect the possibility of food poisoning in the presence of stools of a typically dysenteric character.

3. In this outbreak two distinct types of *B. aertrycke* were found, (1) the Mutton type, and (2) one closely approximating to the Newport type and probably identical with it. The control Newport type "N," of the absorption tests, was, as explained, doubtful.

4. Our records do not contain an instance of a similar outbreak due to cow's milk containing *B. aertrycke*.

THE TOXINS OF *B. DYSENTERIAE* SHIGA.

BY

R. CECIL ROBERTSON, M.D., M.R.C.P. EDIN., D.P.H.,
Pathologist, Bellabouston Hospital, Glasgow.

A REVIEW of the extensive literature dealing with the toxic properties of the *B. dysenteriae* Shiga reveals the fact that various views are held as to the method in which the organism elaborates its toxins and produces its pathological effects. Earlier workers, including Todd, Doerr, Conrad, and Dopfer, seem to favour the view that the soluble toxin of this bacillus is of the nature of an exotoxin. Recent research on the subject by Olitsky and Kligler indicates that two distinct toxins are elaborated by the *B. dysenteriae* Shiga: an exotoxin and an endotoxin, which differ in their action.

This endotoxin is said to be produced when the *B. dysenteriae* Shiga undergoes autolysis or dissolution of the bacterial cell. The exotoxin is said by these workers to be entirely a neurotoxin affecting the central nervous system, whilst the endotoxin is concerned in the production of dysenteric colitis.

Experimental Work.

In order to find out if the observations of Olitsky and Kligler would be confirmed on using the available laboratory strains of *B. dysenteriae* Shiga a well-known toxic strain was selected for the following experiments. The strain chosen was *B. dysenteriae* Shiga, Dean I, and for the sake of uniformity this strain was employed throughout the subsequent experimental work.

Experiments with Exotoxins.—Filtrates from alkaline broth cultures were prepared in the usual way, and 1 c.cm. and 2 c.cm. were injected both intravenously and subcutaneously into rabbits. These animals died within four days, showing symptoms of paralysis but no diarrhoea.

Experiments with Products of Autolysis.—Twenty-four hours' growth from Roux bottles was washed off with saline and the suspensions incubated for two days prior to filtration. The filtrate was heated to 80° C. for one hour. The series of animals inoculated with this filtrate also died, with one exception, within four days. No marked diarrhoea was observed prior to death, but the post-mortem examinations revealed extensive intestinal congestion, affecting principally the caecum and ascending colon. The rabbit which survived was subsequently inoculated with filtrate, which had only been subjected to 70° C. of heat for ten minutes. This animal died within twenty-four hours, showing well-marked diarrhoea, also paralytic symptoms. In order to arrive at an accurate means of estimating the minimal lethal dose of the killed strain of Shiga bacilli used

in subsequent experiments it was considered advisable to adopt weight in fractions of a milligram as a basis comparison. The opacity standards and counting chamber standards are liable to a large margin of error when minute amounts have to be considered.

The method adopted can be briefly stated as follows: A thick bacterial emulsion was prepared from Roux bottle cultivations. This emulsion was made with sterile water and subsequently dried by being exposed *in vacuo* on Petri capsule lids in a desiccator. The dry mass was then finely powdered in an agate mortar, any remaining moisture being driven off by exposure in a dry oven to 30° C. This powder was then stored in sealed glass tubes for further use.

The M.L.D. for a rabbit of approximately 1,000 grams weight was next determined. It was found that 0.01 of a milligram, equivalent to about twenty million bacilli, was just sufficient to kill a rabbit weighing 1,000 grams in three days. This quantity was accordingly counted as the M.L.D., though it was found later that rabbits vary very considerably in their resistance and that occasionally they could survive a slightly larger dose.

It was never found, however, that even a large rabbit could resist more than 0.05 of a milligram of dried Shiga bacilli injected intravenously unless it had been immunized by previous inoculation. Similarly the M.L.D. in the case of subcutaneous inoculation was found to be 1 milligram. In these experiments it was found that the rabbits died with paralytic symptoms, and practically no diarrhoea, and no *post-mortem* lesions of the intestines could be demonstrated beyond a slight congestion. Intestinal lesions did occur in cases of delayed death following partial immunization.

The extreme toxicity of *B. dysenteriae* Shiga has been an important factor in the causes of failure in using this organism in prophylactic inoculation for the prevention of epidemic bacillary dysentery. Very little success has attended any of the measures employed. The failure to produce immunity may be in part due to the fact that bacillary dysentery is not as a rule associated with a general blood infection, as is the case in the enteric group of diseases, but the chief difficulty seems to be in the impossibility of inoculating sufficiently large doses of vaccine owing to the severity of the reactions produced. If any method can be devised which will diminish the toxic properties of the bacillus without affecting its antigenic value, a certain advance will have been made in vaccine prophylaxis.

In 1916 Dean and Adamson found that equal reduced the toxicity of Shiga bacilli; and more recently the results of Thomson in the detoxication of various organisms by treatment with alkali, etc., suggest a similar procedure with regard to *B. dysenteriae* Shiga. Very little work seems to have been carried out along these lines in the case of dysentery bacilli, although they form one of the most important groups for which a non-toxic antigen is required.

In association with Major Coppinger, R.A.M.C., I have found that it is possible to reduce the toxicity of Shiga bacilli by chemical means without seriously reducing their antigenic properties. The method employed does not involve the complete breaking down and solution of the bacilli as in Thomson's detoxicated vaccines.

The method employed is briefly as follows: To a thick emulsion of Shiga bacilli an equal bulk of liquor ammoniac fortis (*L.P.*) was added. The mixture was allowed to stand in the incubator at 37° C. overnight, and neutralization was then effected by means of 20 per cent. sulphuric acid, which, combining with the ammonia, formed ammonium sulphate. No precipitation occurred until the neutral point was reached, when a heavy precipitate immediately formed, which rapidly subsided to the bottom of the flask, leaving a clear supernatant fluid. On separating and washing the precipitate it was found to be composed of bacilli which were altered in shape, but still quite discrete and into rabbits showed that these altered non-toxic, but retained their antigenic properties.

A series of experiments was now commenced with a view to testing the antigenic power of the altered bacilli and determining the most suitable doses for immunizing purposes. The immunizing effects were estimated by injecting toxic Shiga bacilli into rabbits previously inoculated with the now antigen, and judging from the results the degree of protection which had been conferred. In the absence of symptoms the condition of the rabbits was judged by the weight, an accurate daily chart of which was kept in every case. A series of rabbits was inoculated, five subcutaneously and five intravenously, with ammonia-treated bacilli. All the rabbits inoculated subcutaneously survived and suffered from no obvious reactions, either local or general, though in each case a distinct drop in weight occurred for a few days after the lethal test dose, which was subsequently injected intravenously. Three of the series injected intravenously died after the first inoculation, which was apparently

too large. But the two which had received 0.1 mg. survived, and afterwards received larger doses without showing any ill effects. Moreover, the protection conferred was greater than in the case of the subcutaneously injected rabbits, as was judged by the fact that the injection of the lethal test dose produced no loss in weight. An attempt was now made to test the antitoxic effect of serum obtained from the seven rabbits surviving from the above experiments. Serum obtained from each of the rabbits was pooled and 1 c.cm. of the pooled serum injected into each of three normal rabbits along with 0.8, 0.4, and 0.1 mg. of unaltered Shiga bacilli respectively. The first two rabbits died, but the animal which had received 0.1 mg. (10 M.L.D.) survived, showing that the serum had acquired some degree of antitoxic power.

Human experiments on any large scale have not yet been carried out, but one of us received injections of 0.03, 0.075, 0.15, and 0.3 mg. of treated Shiga bacilli (approximately equal to 60, 150, 300, and 600 million) without any reaction beyond a slight local tenderness and induration, which, in the case of the largest dose, persisted some days.

Summary.

1. The observations of Olitsky and Kligler have been in the main confirmed, although it has been found almost impossible to produce "exotoxin" without at the same time having present a considerable quantity of the neurotoxin or "exotoxin."

2. Although two definite toxins for animals may be produced by Shiga bacilli, there is considerable evidence that the neurotoxin or "exotoxin" has a secondary action on the intestine through the initial inhibition of peristalsis prior to the passing of mucus or desquamated epithelial debris. The animal usually dies before the effect on the intestine becomes characteristic.

3. The oral administration of living Shiga bacilli to rabbits does not produce dysentery or any demonstrable serological reaction.

4. The toxicity of the bacterial substance of dried Shiga bacilli is not lessened by the treatment with acetone or the subjection to 100° C. for twenty minutes.

5. The various means of producing a detoxicated antigen from the bacterial substance appear to depend on the principle of macerating the bacillus with a strong alkali, then to neutralize the solution, and to utilize the resultant precipitate of less toxic bacterial substance.

6. The detoxication is only relative, but it affords a means of producing a vaccine which is useful in commencing the active immunization of animals. The intradermal reaction with this vaccine is not severe and large subcutaneous doses can be given without local reaction.

In conclusion, I beg to acknowledge my indebtedness to Sir William Leishman and to the professor of pathology at the Royal Army Medical College for assistance and encouragement in carrying out this experimental work.

THE DEVELOPMENT OF LOA LOA IN CHRYSOPS.

BY

A. CONNALL, M.D., D.P.H., D.T.M. and H.,

AND

S. L. M. CONNALL, M.B.E., M.A., B.Sc.

(From the Medical Research Institute, Lagos, Nigeria.)

[Abstract.]

THE adult *Loa loa* lives in the connective tissues of man. The disease known as Calabar swelling is held to be due to the presence of this worm. In the course of its wanderings, it occasionally crosses the eye, where it can be seen making its way under the conjunctiva. The female is longer than the male (about 2½ inches long), and is viviparous. The young make their way into the blood stream and are to be found there in greatest numbers during the daytime, hence their name, *Microfilaria diurna*. These embryos cannot develop further unless they find their way into another host. That host has been proved to be one of the Tabanid family of blood-sucking

flies, Chrysops. The geographical distribution of *Loa loa* and of Calabar swelling is limited to West Africa, and in certain areas of Nigeria the incidence is high. The investigations now to be shortly described were carried out in Nigeria during 1921.

Large numbers of Chrysops were allowed to feed on human cases in whose blood the embryos were present. Each fly was allowed to gorge itself on the patient. It was found that a rapid and uniform development of the embryos took place in all the flies (over 300) which were examined. The complete metamorphosis occupies a period of ten to twelve days. As ten days is the usual length of the cycle, it will be convenient to describe the changes from the first to the tenth day. Within an hour or two of passing into the stomach of the fly along with the ingested blood the embryos show active movements, which eventually enable them to cast their sheath. After a short period of comparative quiescence they penetrate the stomach wall of the insect and make their way to its muscular and connective tissues.

By the end of the first day most of the embryos are to be found near the tip of the abdomen, but they also occur in the thorax and in the head. The worm is now somewhat shorter than the original embryo, but thicker in its posterior third and with a finely drawn out curved tail. During the second day considerable thickening occurs and also an increase in length. Two vacuoles appear, one anteriorly and the other posteriorly. During the third day the worms grow still longer and thicker, and an alimentary tract develops. The alimentary canal is a slightly sinuous tube continued from the simple mouth at the anterior extremity backwards to the posterior vacuoles, where it ends in an anus. During the fourth and fifth days there is a greater increase in length than on the previous days and a lesser increase in breadth. On the sixth day the worm again casts its outer covering, and emerges with a trilobed tail, whilst the vacuolated areas have disappeared. On the seventh day a wide range of movement appears to be possible, and individuals may be found in the legs and in the roots of the wings of the insect. Up till the tenth day rapid lengthening occurs, with little or no increase in breadth. By the end of this period the worms are to be found congregated mostly in the head, at the root of the proboscis, and down into the labium. When next the Chrysops proceed to suck blood the young filariae swarm down through the labium and labella of the fly and pass on to the skin. Within a very few seconds they make their way through the pores into the tissues, where they proceed to develop into the adult form.

A full account of the foregoing investigations, along with references, will be found in the *Transactions of the Royal Society of Tropical Medicine and Hygiene*, 1922.

THE INTIMATE STRUCTURE OF THE BACTERIAL CELL.

BY

DAVID ELLIS, D.Sc., Ph.D., F.R.S.E.,
Royal Technical College, Glasgow.

In spite of the extreme minuteness of the bacterial cell it is still possible to obtain a fair amount of information regarding its intimate structure. It must be confessed that this information cannot all be derived from a single species, and that the final picture is built up from material supplied from several sources. In order to get the best results the highest powers of the microscope must be directed on properly stained material by the light of a white cloud in the middle of the day during the summer season. The staining of the cell is very simple, but it must be carried out very carefully, and it must be borne in mind that the end in view is not necessarily the staining of the cell but rather the differentiation of its parts. The various constituents do not take up stains at equal rates, so that it is possible to obtain a differentiation of parts, which, however, persists only for a short time. With the continued penetration of the dye all parts become more or less uniformly stained and the differentiation is lost. The best results are obtained by the use of iodine solution, this fluid being allowed to penetrate slowly from the sides of the cover-slip. It is helpful to bear in mind that the bacteria are either generally regarded as primitive or degenerate members of the plants classed under fungi, and that we may thus expect that the general structure of the intimate parts of the bacterial cell will resemble that of the cells of this group.

It is generally agreed that the lower bacteria consist of three distinct groups: the Bacteriaceae, including the rod forms; Cocciaceae, including the spherical forms; and Spirillaceae, including the spiral forms. It may be stated at the outset that the Bacteriaceae and Cocciaceae form a natural group with very close affinities among its members, but that the group Spirillaceae is evidently widely divergent in its affinities. This fact is borne out in a most marked manner by the study of the intimate structure of the cells. Lastly, we have to take into account the intimate structure of the cells which make up the various thread bacteria.

The structure of the bacillus, the most typical of the Bacteriaceae, will be considered first. Its plant nature, and in particular its affinity to the fungi, is exhibited at every point. The cell is delimited on the outside by a sharply defined membrane which is shown very clearly by staining with any one of the usual dyes. It can be separated from the body of the cell by plasmolysis. It is elastic, as it is easily stretched and as easily returns to its former shape when the cause of the stretching has been removed. This, of course, is an obvious necessity in the membrane of a motile rod. It offers very little resistance to the escape of solid enclosed bodies to the outside. This can be observed when the application of a stain causes a greater swelling of the body of the cell than of the membrane. Bodies immersed in the former are sometimes pressed against the membrane and make their way out. Further consideration of the membrane will be postponed until we have dealt with the other cell structures. The body of the cell is made up of cytoplasm, which, however, is not homogeneous. By careful staining it is possible to make out a vacuolar network, such as is discernible in the cells of higher plants. In the vacuoles are doubtless located the same class of substances which are found in the vacuoles of higher plants—namely, raw materials, reserve materials, and other metabolic products, the formation of which is inevitably associated with plant or animal metabolism. In the cytoplasm of the bacillus the finer granules, plastids, etc., which have been observed in higher plants have not been discovered. We do, however, find solid particles of these reserve materials that are accumulated in quantity in the cell. These are *volutin*, the nitrogenous reserve material; *glycogen*, the carbohydrate form; and *oil globules*. These are the three main reserve materials in bacterial cells and are sometimes massed in fairly large quantities.

The question of the presence or not of a specific nuclear body is still a somewhat vexed one. It is certain that we are not likely to be able to settle the question by identifying the intimate structure of the nucleus in the bacillus with that of the nucleus of higher plants. It is, of course, not certain that if present the nucleus of the bacillus would conform to the highly complex nucleus which characterizes the cells of the higher plants. So far as can be judged from the information obtained by direct observation of the cell, all that can be stated is that in the cells one or more round bodies have been discovered which are different from the other bodies known to be present, and which take up the same stains as do the nuclei of higher plants. They are also present in the same relative proportion as are the nuclei of fungal cells. It comes to this, that the acceptance of the nucleus in bacterial cells is largely a matter of temperament. The strongest ground for acceptance appears to me to lie in the fact, which I now propose to discuss, that there appears to be a nucleus in control of the process which culminates in the formation of an endospore. As is well known, bacteria reproduce asexually by the formation of spores inside the cell. This process is common among the Bacteriaceae, so far as is known, is confined to one species among the Cocciaceae, and is unknown among the Spirillaceae. In all cases spore formation is heralded by the appearance in the cytoplasm of a round or oval area which equals in volume the space occupied by the completed spore. This clear space is easily discernible by careful staining, with the end of intensifying the opacity of the cytoplasm, which in consequence makes the clear area more visible. The next stage in the development of the spore is a gradual absorption by something inside the clear space of material from the surrounding cytoplasm, with the result that the next stage in the development shows that what in the first stage was a clear space is now more opaque than the surrounding cytoplasm; and further, that the latter stains far less deeply than was the case in the first stage. It is clear, therefore, that the spore area once formed is capable of absorbing material unto itself, just as a solution of sugar contained in a permeable bag and

surrounded by water is capable of absorbing the latter substance until a certain pressure equilibrium has been reached. When the spore area is first formed it doubtless contains osmotically active substances which cause the absorption of certain ingredients which are necessary for the production of a spore. It is also obvious that the absorption is effected under the regulating influence of living matter, inasmuch as the completed spore contains living matter, and at no stage in the development of the spore is provision made for the introduction of protoplasm. Such being the case, the protoplasm must be present in the clear area when this is differentiated from the surrounding cytoplasm. The investigation into the spore development in the bacillus has shown that there is in the centre of the spore area a round substance, and this round substance has six or seven points on its periphery which suggest the remains of radiating strands from the round substance to the periphery of the spore area. The complete strands have not yet been observed, which is not surprising in view of the extreme minuteness of the organs under investigation. I may state that the same features have been observed in the only species among the Cocciaceae which forms spores—namely, *Sarcina urinæ*.

If we accept what the facts just mentioned suggest, then the spore area is a cell, the round object in its middle is a nucleus, and the points which beset the round object are the remains of cytoplasmic threads. In the third stage the effects of the osmotic activity are visible, inasmuch as the young spore—as we may now term the spore area and its contents—becomes deeply stained, whilst the rest of the cell is only extremely faintly coloured on the application of the appropriate dye. The spore has absorbed practically the whole of the contents of the cell. In a still further stage the spore is seen to be lying in an empty shell. By this time it has become surrounded by a well-defined membrane, and further, the membrane itself is made up of two layers, an inner thin one and an outer thicker one, which is often sculptured, in some species in a manner which can be used for the identification of the species. It is to the presence of the spore membrane that the resistant nature of the spore is due. The shell in which the spore is enclosed is the membrane of the cell in which the spore was formed, and if any doubt remained as to the presence of a specific membrane in the cell a glance at a spore lying in a bacterium from which everything had been abstracted except the membrane would settle the point. It is very curious to observe one of these spore-containing cells in a state of motility when it is practically empty of everything except the spore. There must, of course, in such cases be a fragment of cytoplasm still remaining in the cell, and it is to such a fragment that the flagella, the undulations of which have caused the motion are attached. In course of time the cell membrane disappears and the spore is free. During germination the outer membrane of the spore is cast, whilst the inner membrane becomes the new membrane of the new bacterial cell that is formed as a result of the germination.

We may, I think, adduce the fact that a small round object is found in the middle of the spore area, together with the fact that this spore area becomes a body which is endowed with life in support of the contention that the bacterial cell possesses a nucleus. The various facts that have been brought forward to prove the presence of a nucleus lend mutual support to one another, but it must be confessed that all doubts cannot be regarded as abolished.

A subject worthy of attention is the mode in which large quantities of volutin, oil globules, and glycogen are formed in the cell; and, further, the relatively enormous quantities of sulphur globules that are present in the sulphur bacteria when these organisms are in their prime. So far as the first three reserve materials are concerned, their formation appears to be by direct secretion from the protoplasm. There appear to be no special plastids concerned in the process such as are found in the leaves of plants when starch grains are formed. The presence of special plastids is not necessary even in all cases where starch is formed, so that we need not be surprised that direct secretion from the protoplasm should be the rule in the formation of bacterial reserve matter. In any case no plastids of any kind have been discovered in bacterial cells. We have seen that the spore is formed by the absorption of matter into a previously prepared area, and it is possible that this method may be the rule in the formation of reserve matter, although it is not probable. The case, however, is different when we come to consider the formation of reserve matters among some of the higher bacteria. The formation of sulphur in the sulphur bacteria follows the

absorption of sulphuretted hydrogen, which is oxidized under the influence of living matter into sulphur. This sulphur is stored, but is gradually used up and converted into sulphates. The formation of sulphur is a far less complicated process than that of volutin or glycogen, and its collection appears to be of the nature of secretion into a prepared area, only that the osmotically active substances are not controlled by living matter, as seems probably the case in the formation of the spore. There is invariably found a clear area surrounding each sulphur globule in the cell separating it from the surrounding cytoplasm. When a sulphur globule has been used up by the cell a gap is formed which is larger than the sulphur globule which first occupied it. It is possible, of course, to give another explanation to this fact, such as, for example, that the sulphur globule had contracted after its formation; but it seems to me that the most reasonable explanation is that a space is cleared in the cytoplasm which contains osmotically active substances, and that these have a selective action on the sulphur formed during the first stage in the metabolism of the absorbed sulphur compounds.

In our consideration of the bacillus we must not forget that outside the sharply defined membrane there is a covering, normally very thin, of mucilaginous matter doubtless formed by the degeneration of the outer portion of the membrane. This layer is very difficult to stain, but its existence is made evident when two cells are observed in the coils of division. The two newly separated daughter cells do not appear to be able to effect complete separation for some time after they have come apart and the cause is to be traced to a filament of mucilage which binds them. There seems little reason to doubt that the intervention of unfavourable conditions increases the amount of this substance which is formed and so increases the power of cohesion of the cells. The results which were outlined above as following the frequent subculture of bacterial species were evidently due in the first place to the absence of this mucilaginous substance in any appreciable quantity; and this in its turn caused the absence of cohesion of the cells, which was such a marked feature in the cultures after this treatment. It seems to me that the varying results, which so often accrue when different analysts estimate the disinfecting value of certain commercial fluids, is due to the varying amounts of mucilage outside their membranes which the cells of different cultures of the same species possess.

The intimate structure of the cocci tallies so closely with that of the bacillus that no doubt exists as to the close genetic connexion of the Bacteriaceae and Cocciaceae. The differences are only such as are inseparable from the cylindrical form of the one and the round form of the other. The methods of cell division and of spore formation are identical in every respect. The tendency to form groups, either regular or irregular, is not natural to the Cocciaceae, as I have explained elsewhere, can be eliminated altogether by cultivating under conditions which prevent the formation of this mucilage in any quantity. The demonstration of the vacuolar nature of the cytoplasm has not yet been accomplished. In the formation of the spore the presence of the spore area has been noted, and it has been ascertained that the same stages in the formation of the spore are followed. It is evident that the massing of the cocci into clumps destroys motility, but when this massing together is prevented, as explained, movement follows.

We come next to the third group, of which the genus *Spirillum* is the most typical member—namely, the Spirillaceae. The intimate structure of the spirillum is on a plan which is totally different from that found in the other two groups. There is an outer limiting membrane, but it is doubtful whether it differs in kind from the inner part of the cell. When cell division takes place the membrane plays no part whatever and the cell behaves as though it were devoid of a membrane altogether. Division takes place by a complete separation of the cell into two completely rounded off portions connected by a thick bridge of mucilaginous matter shaped like a concave lens. The size and form of the cell remain unaltered during the process and the formation of the two daughter cells seems to take place very rapidly. The remainder of the process is merely a gradual separation of the two newly formed cells. These gradually move apart under the influence of the flagella. The lenticular bridge of the mucilage under the influence of the tension between the two new cells becomes more and more attenuated until very often the space between the still connected cells is greater than the length of the cells themselves. By staining with fuchsin all stages in this separation can be followed.

Ultimately the connecting cord is broken and the two cells become completely separate. It is evident that the division of the cell is accomplished by simple partition which takes place very rapidly, and there is a complete absence of that elaboration which marks the cell division of the Bacteriaceae and Coccaceae. It has not hitherto been found possible to demonstrate any differentiation in the groundwork of the cell, although it has been stated that a nucleus comparable to the body called by the same name in the bacillus can be distinguished from the reserve products (volutin and oil drops) which are found in the spirillum. The scheme of the structure that prevails in the Spirillaceae is thus markedly different from that which prevails in the other members at present included under Bacteria. The Bacteriaceae and Coccaceae are typical plant groups, but it is not improbable that in the future claims may be advanced by the zoologists for the inclusion of the Spirillaceae in their domain.

Finally, we come to the thread bacteria, which are distinguished from the lower bacteria which we have discussed above, in some forms by the cohesion of the cells to form a community, in other forms by the greater length and size of the cells. The cells of the thread bacteria show no division of labour. The cause of the cohesion of cells in those thread bacteria which consist of cell communities is to be traced to the further development of the mucilaginous covering which we saw was not absent from the lower bacteria. This covering hardens in such organisms, and thus prevents the escape of the dividing cells. We have, therefore, a filament of cells, each cell possessing its own membrane, and the whole row of cells surrounded by an envelope of hardened mucilage. I have established the identity of this substance with the mucilage which surrounds the bacillus by finding its presence between the cells of *Cladothrix dichotoma* as well as on their sides. The individual cells of such organisms as *Cladothrix* and *Crenothrix* do not differ in any essential detail from those of the bacillus. So far as the information which we at present possess gives us any clue to affinities it may be said that the iron bacteria as a class are more closely related to the Bacteriaceae, but that the sulphur bacteria adhere more closely to the Spirillaceae, and therefore, to my mind, are as much to be regarded as representatives of the animal as of the plant kingdom.

I have not had any opportunities of examining the internal structure of other genera of the higher bacteria, and unfortunately the amount of knowledge of these forms is very meagre. It is to be hoped that this state of matters will be remedied in the future.

SECTION OF TUBERCULOSIS.

SIR ROBERT PHILIP, M.D., LL.D., P.R.C.P. Edin., President.

PRESIDENT'S INTRODUCTORY REMARKS.

THIS is the first occasion when at a meeting of the British Medical Association a Section has been devoted to tuberculosis. The time at the disposal of the Section is short. I do not propose therefore to occupy more than a very few minutes by way of introduction. The institution of the Section is a fact of much significance and merits emphasis. When the Association met last in Glasgow in 1888 such a Section was undreamt of. Recall how things stood then. The tubercle bacillus had been determined six years before, but little practical heed had been given to the discovery. The first tuberculosis dispensary had just been established and the sanatorium was beginning to be spoken of.

How remarkably the situation has changed since then! The bacillus has been the object of countless researches and forms the centre of a vast literature. The tuberculosis dispensary is an accepted institution throughout the world. It has been reproduced by thousands. Sanatoriums and their congeners, hospitals, tuberculosis schools, and working colonies have sprung up everywhere. In Great Britain the necessity of linking the various institutions has been officially recognized. Tuberculosis schemes, which include the several institutions variously grouped, and a tuberculosis service with duly accredited officers, have been established by statute. Tuberculosis now occupies a place in the group of infectious diseases, and notification of the disease in all its varying forms is compulsory.

During 1921 in England and Wales the number of notifications of tuberculosis amounted to 71,702, and in Scotland 12,524.

On June 1st, 1922, tuberculosis schemes in England and

Wales included 381 tuberculosis officers, 441 tuberculosis dispensaries, 84 visiting stations, and 20,395 beds in sanatoriums, hospitals, etc., with 2,664 additional beds in preparation. At the same date in Scotland tuberculosis schemes included 80 tuberculosis officers, 29 tuberculosis dispensaries, and 3,558 beds in sanatoriums, hospitals, etc. In addition to this official provision there are many beds available and much collateral effort on the part of voluntary agencies.

The medical student of to-day receives special training in the subject. At the University of Edinburgh attendance on a course of thirty meetings forms a compulsory part of the medical curriculum. Societies for the study and prevention of tuberculosis have been established in most countries, and an international union embracing representatives of over forty nations is in active being.

A single word as to the main facts concerning mortality from the disease during the period under review. The drop in the death rate in the interval since the Association met last in Glasgow is remarkable and reassuring. During the period from 1881 to 1890 the average number of deaths from all tuberculosis in England was 66,526—that is, 242 per 100,000. In 1919 the number of deaths was 46,310—that is, 126 per 100,000. In Scotland the corresponding figures are: for the period 1881–90, 10,645 deaths—that is, 276 per 100,000; and for 1919, 6,326 deaths—that is, 129 per 100,000. Or stated otherwise, if we take 100 as representing the average death rate from all forms of tuberculosis in each country for the period 1881–90, the mortality for 1919 in the case of England works out at 52 and in the case of Scotland at 47. These striking records are still more remarkable in view of the more accurate and exacting methods of diagnosis which have followed the advance of knowledge regarding the etiology and nature of the disease.

The study of tuberculosis, which in 1888 was considered by many as practically exhausted, flat, dull, and unprofitable, is now alive and progressive. The recognition of the subject at the Annual Meeting of this great Association is therefore abundantly justified.

DISCUSSION ON THE CLINICAL DIFFERENTIATION OF PULMONARY TUBERCULOSIS FROM OTHER RESPIRATORY AFFECTIONS.

OPENING PAPER

BY

E. RIST, M.D. PARIS.

NOT very many years ago the diagnosis of lung tuberculosis from other respiratory diseases seemed a rather trite and certainly little inspiring subject for discussion. That it should have been chosen as one of the topics of the day at this meeting is in itself sufficient proof that some important changes have taken place in our theoretical and practical knowledge of tuberculosis. Even before the world war premonitory signs of those changes were not lacking, although they were perhaps evident only for the naturally limited circle of medical men who specialized in the scientific study of consumption. But it is certainly due to the experiences of the war that the recognition of an urgent need for remodelling our diagnostic methods has been forced upon the profession as a whole, and, I may add, all over the civilized world.

Not only when the hugest and best-equipped armies which history has ever seen entered the field, but even from the moment they were formed, gathered into camps and barracks, and trained, the problem of tuberculosis had perforce to be considered in a new light by the medical officers responsible for the selection of men, for the physical efficiency of recruits, and, last but not least, for the future liabilities of the respective Governments under the Acts providing for pension and insurance in favour of soldiers disabled by disease. Consumption is a chronic malady. Unfortunately it cannot be cured by any of those radical, immediate, clear-cut methods which make it an urgent duty to diagnose early and exactly and to treat deliberately and promptly some of the diseases which modern medicine can to a certain extent boast her ability to conquer: diphtheria, malaria, syphilis, appendicitis, for example. Although we were theoretically prompted by our teachers to look for early signs and not to delay treatment, in everyday

actice the "wait and see" policy was almost universally applied to lung tuberculosis. Individual cases were for protracted periods regarded as merely suspicious. Treatment, which so often entails a total change in the material and moral life of the patient, with considerable sacrifices and expenditure, was advised late—in many instances too late. We all know that, by another school of physicians, it was—and still is—often imposed uselessly on people who do not need it, on the ground that it is better to prevent a possible outbreak of tuberculosis than to try to arrest it when fully developed.

The necessities of war have put before us the duty of rapid, well-founded, uncompromising decision in matters of tuberculosis diagnosis. No belligerent State could afford to keep thousands of men under expectant observation in order to decide whether, after several weeks or months, they would be rejected from or admitted into the ranks. No belligerent State could afford to admit into the army men who not only would be unfit to serve but would spread contagion among their comrades. Nor could they afford to deprive themselves of the services of any man who was really fit to be a soldier, and to reject him on the ground of some spurious suspicions which events would prove unfounded. For obvious reasons considerations of the same kind had to be borne in mind in the case of men who fell ill when serving. If really tuberculous, it was in the interest of the army as well as of the State that a correct diagnosis should be made as soon as possible, in order that they should be discharged and treated without delay. If not tuberculous, the same joint interests imposed upon the medical officers the duty of making an accurate and early diagnosis, in order that mild, transient, and curable non-tuberculous respiratory disease should not have as its consequence discharge and pension, and that more serious non-tuberculous disease should be, whenever amenable to cure, treated judiciously.

I am sure nobody will feel shocked or surprised if I say that, as a rule, medical officers were not well prepared, in the early days of the war, to meet these new duties. It soon became evident that mistaken diagnoses in the matter of long tuberculosis were all too numerous. The mistakes were not always in the same direction. Of course—and this had been generally foreseen—many cases of consumption were overlooked. But the fact that a considerable number of cases labelled at first "tuberculosis" and disposed of as such were ultimately proved not to be tuberculous at all was certainly quite unexpected, even to the majority of tuberculosis experts.

That the proportion of errors in the routine diagnosis of lung tuberculosis is apt to be very large, some figures, which I intend to give later, will illustrate. At the present time my purpose is only to remind you how the experiences of the war convinced the majority of us that there was something wrong in our everyday methods of discriminating tuberculosis from other diseases and more especially from other respiratory diseases.

NEW POINTS OF VIEW CONCERNING PULMONARY TUBERCULOSIS.

As a matter of fact, new and important knowledge had been slowly gained in various fields of pathology and clinical investigation, but we had failed in adjusting our diagnostic procedures to this knowledge. What I mean can be conveniently summarized under four heads.

1. The Skin Reaction.

The skin reaction to tuberculin has proved that tuberculous infection, at least among civilized communities, is almost universal. We are now aware that the first infection is generally accomplished during the first fifteen or eighteen years of life, but that it is followed by tuberculous disease in only a small number of exposed individuals. That a mild first infection confers an immunity which protects the majority of adults against further infection and disease is a well-ascertained and generally admitted fact. It seems most probable that the mildness of a primary infection is not due to a hypothetical attenuated virulence but to the small number of germs, heavy infections determining severe, generalized, and, as a rule, lethal forms of tuberculosis in children as well as in adults hitherto non-exposed—as, for instance, natives of non-civilized countries. A positive skin reaction, therefore, cannot be considered as a diagnostic sign of tuberculous disease, but only as an index

of tuberculous infection. In other words, we must discriminate between infection, which is almost universal in the civilized adult, and disease. The earliest beginnings of disease are not as was supposed, coincident with those of infection. The once prevalent idea that early diagnosis—and, as its consequence, early treatment—should endeavour to discover and to ascertain the initial steps of infection has proved a fallacy. We are now able, thanks to the skin reaction, to recognize tuberculous infection almost at its beginning. But, contrary to the expectation of fifteen years ago, we are led to admit that the infected individuals which the von Pirquet test discovers are more protected against subsequent tuberculous disease than the non-infected. The whole problem of early detection of lung tuberculosis must consequently be considered from an entirely different point of view.

2. The X Rays as an Aid to Diagnosis.

X-ray examination of the chest has—slowly, indeed, but persistently and successfully—gained its legitimate place among our methods of physical diagnosis. The instruments and the technique have been improved to a considerable degree. An increasing number of physicians have taken up the study of fluoroscopy and radiography. Of course some of us are still reluctant, and ask for x-ray information only as a last resource in exceptional cases. A century ago auscultation was also regarded as a last resource by many who, apparently, were not mindful that

"There are more things in heaven and earth, Horatio,
Than are dreamt of in your philosophy."

To appreciate the real value of a new method of physical diagnosis, there is only one way, and that is to use it regularly and persistently together with the classical methods, in ordinary and simple not less than in rare and complicated cases. Not only the so-called x-ray expert, but the clinician as well should master the technique of fluoroscopy and train himself in the reading of plates, constantly controlling the information so obtained by the ordinary physical examination and by *post-mortem* findings. Fortunately this is being done more and more; there are already physicians who think that a chest has not been completely examined if it has not been x-rayed, and who act accordingly. I may be perhaps allowed to confess that, for my part, I have adhered to that principle these last fifteen years, and that all the patients whom I have examined, either in hospital or dispensary work or in private practice, have been x-rayed by myself.

No wonder if the prolonged use of the fluoroscope and the plate has gradually modified our views concerning the practical value of other methods of physical examination. One has to admit that percussion and auscultation have their limitations and pitfalls; one cannot deny that the x-rays are able to inform us rightly in many cases when the older methods leave us doubtful or mislead us. Even when the rays only confirm what auscultation and percussion reveal, they help us by adding weight to our argument. But when the results of x-ray information and of classical physical examination are contradictory, which is often the case, we ought not simply to disregard the first, but to reconsider the second, in the light of that contradiction. This practice has led to a great deal of new knowledge. I may mention the discovery by the fluoroscope of deep-seated lesions which the ear is unable to detect, the now well-established fact that cavitation is generally much earlier and much more frequent than was supposed, or that consolidation in tuberculosis is, as a rule, more extended than one would think, if one were guided only by the stethoscope. On the other hand, there are cases when râles and other adventitious sounds suggesting an extended, parenchymatous lesion do not coincide with any abnormal x-ray finding, and where consequently we have to ask ourselves whether the acoustic phenomena are not merely symptomatic of bronchial catarrh, without any alteration of the lung tissue. To interpret rightly the sequence of events in the evolution of lung tuberculosis we must therefore take into account the treasure of valuable information with which the x-ray exploration of sound and diseased chests has enriched our knowledge. At the same time we must take advantage of the powerful aid which the rays have brought us in the diagnosis of non-tuberculous chest disease.

3. Examination of Sputum.

There has been lately a general tendency to attach much more importance than one did before to the demonstration of tubercle bacilli in the sputum of consumptives. Our methods of detection have been improved. Homogenization of the sputum, inoculation of the guinea-pig, are now widely used. Laboratories are at the disposal of the greater part of the profession. A complete examination of a supposed tuberculous patient implies repeated and conscientious sputum examination. The result of this close association between the bacteriological laboratory and the bedside or dispensary practice has been to show us that bacilli appear in the sputum much earlier than was admitted before, and consequently to throw some doubt on a diagnosis of tuberculosis which has not been corroborated by the demonstration of the causal micro-organism in the morbid secretion. Not many years ago, when physical examination elicited the signs of a lung lesion, and when some of the symptoms of consumption, such as fever, hæmorrhage, coughing, and wasting were present, one thought oneself perfectly justified in considering the diagnosis of tuberculosis certain, even if no bacilli could be demonstrated; as a matter of fact, one did not always take the trouble of looking for them. We are less inclined to do so now. An open lung lesion where no bacilli can be found we regard as a problem which cannot always be easily solved. It obliges us to discuss the possibility of a disease other than tuberculosis. I shall even go farther: it makes that possibility very plausible.

4. Infections of the Upper Respiratory Passages.

The nose and throat specialist has become an appreciated guest at the medical symposium. He has improved his instruments, his technique, and his knowledge. The diseases of the upper respiratory passages have asserted their frequency and their importance. The nasal cavities belong to the breathing apparatus as well as the lungs. Their infections, catarrhs, and mechanical obstructions influence the bronchial tree, and even the alveolar tissue, quite as naturally as the maladies of the urethra and prostate influence the bladder and kidneys. There is no real frontier between the province of the nose and throat specialist and the empire of the lung expert. The more one studies bronchial and lung pathology the more one gets convinced of the interdependence of all the parts of the respiratory tract. The realization of this apparently so self-evident but unfortunately so long overlooked truth has contributed to no small extent to changing our points of view regarding the diagnosis of lung tuberculosis.

THE MODERN CONCEPTION OF TUBERCULOSIS DIAGNOSIS.

I think the views which have just been summarized are more or less shared by an increasing number of those physicians who have specialized in the study and diagnosis of lung tuberculosis. I say more or less, because, according to their personal tendencies, they would naturally lay more stress on one or two of my four points rather than on all of them. In order to ascertain to what extent the conception—which I would venture to call the modern conception of tuberculosis diagnosis—differs from the traditional, one has only to study the statistical figures which have been published recently by those well-equipped clearing stations or hospitals where, in many countries, service or ex-service men are now submitted to observation before discharge, admission on the pension list, or treatment. I shall quote a few instances.

In 1916 I was conducting, in the capacity of an army consultant, a tuberculosis clearing station at Compiègne. Out of 192 men sent in with a diagnosis of lung tuberculosis from various army units, ambulances, or hospitals, and kept under observation, this diagnosis was found to be justified in 53 cases only (or 27.5 per cent.). I may mention that this figure includes arrested and healed as well as active tuberculosis; 139 cases (or 72.5 per cent.) were undoubtedly non-tuberculous.

During the summer and autumn of 1918 I acted in the same capacity at the Laënnec Hospital, for the troops stationed in Paris. Of 382 men examined, 37 only (10.8 per cent.) had lung tuberculosis; 22 (6.4 per cent.) were not definitely diagnosed because the time during which they were kept under observation was too short; 283 (82.7 per cent.) were certainly not tuberculous. During the winter 1919-20, 119 men who had been proposed by medical officers for pension on the

ground of lung tuberculosis were referred to me and taken into my hospital wards: 47 per cent. were tuberculous. 53 per cent. were not.

My friend Professor Sergeant acted, during the greater part of the war, as the chief physician of a tuberculosis clearing hospital for French soldiers. Out of 1,719 men, he found 542 (31 per cent.) who were not tuberculous. Among the 69 per cent. tuberculous men, more than one-half had healed lesions which did not justify a discharge from service.

Dr. Dickinson, tuberculosis officer of Newcastle-upon-Tyne, very kindly supplied me with the following information concerning the ex-service men who applied in Newcastle for sanatorium benefit between the years 1913 and 1919. Out of 287, 167 had bacilli in their sputum, and 120 had none. Of those 120 men, 91 (or 75.8 per cent.) were ultimately proved to be non-tuberculous. Among the 167 who had bacilli 53 died; among the 120 whose sputum was free from bacilli 4 only died; the causes of death in these 4 cases were respectively bronchiectasis, influenza, sarcoma of the lung, disseminated tuberculosis.

In the report of the Public Health Committee of the London County Council for 1921 we read the result of observation of 158 ex-service and insured London cases sent, for diagnostic purposes, to the Brompton and City of London Chest Hospitals during the year 1920. Of 158 cases, 124 (or 78.4 per cent.) were reported as not suffering from tuberculosis. Of the 34 cases diagnosed as tuberculous 10 were considered to be "arrested" cases not requiring treatment; only 24 (or 15 per cent.) of the 158 cases being recommended for treatment.

I have limited my quotations to Great Britain and France. But I could have given you figures quite similar from Swiss, Italian, or American sources. The discrepancies which they illustrate are universal. Of course, it would be absurd to imagine that they are peculiar to the limited group of service and ex-service men. The diagnostic criteria which are commonly applied to those men before they are referred to special diagnostic centres are quite as widely used in ordinary civilian practice, and they lead to a similar proportion of mistakes. At the out-patient consultation for lung disease which I conduct at the Laënnec Hospital alongside with my in-patient department, I find that 62 per cent. of the cases referred to me by tuberculosis dispensaries or private practitioners as consumptive suffer from diseases which have nothing to do with tuberculosis. A large number of them have nevertheless been treated, sometimes for many years, as if they were tuberculous; they have been the occasion of considerable—and perfectly useless—expenditure of money at their own or at public expense; they have been submitted to all the hardships, restrictions, moral and material sacrifices which attend the life of a tuberculous patient; and finally they have not even received the proper treatment which the real disease they suffered from required.

DISEASES MISTAKEN FOR PULMONARY TUBERCULOSIS.

The question we have now to ask ourselves is: Which are the commonest diseases which are so often mistaken for lung tuberculosis? They fall under three heads.

In the first place, we find ailments which are not caused by morbid conditions of the respiratory system, but have some symptoms in common with those of such conditions, or determine secondary lesions of the lung or pleura. I may briefly mention the diseases of the cardio-vascular apparatus: dyspnoea, coughing, thoracic pain, hæmoptysis belong to their symptomatology. They are not infrequently complicated with bronchitis, pleural effusions, passive congestion, oedema of the lungs, or lung embolism; these, of course, are manifested by physical signs which are apt to mislead one when the symptomatology of the causal disease remains obscure as is sometimes the case. Let me remind you, for instance, of the blood-spitting which so often occurs in mitral stenosis, or of the lung embolism concurrent with prolonged fever which is one of the features of malignant endocarditis. Diseases which are associated with wasting, loss of appetite, and progressive weakness, such as cancer of the digestive apparatus, conditions which determine loss of weight, instability of the body temperature, tachycardia, like Graves's disease, should also be taken into account. But, vast and interesting though this category undoubtedly is, it does not fall within the scope of the present discussion.

We are properly concerned, on the contrary, with the second group—namely, non-tuberculous diseases of the intrathoracic respiratory apparatus, whose signs and symptoms are for the greater part identical with those of the manifold forms of lung tuberculosis. Some are exceptionally met with:

Syphilis of the lung, for instance, has absolutely no signs of its own, and therefore it is almost regularly regarded as tuberculosis, until the repeatedly negative examination of the sputum for bacilli opens the door for suspicion into the mind of the physician. In many published cases the surprisingly rapid cure of the lung ailment under the influence of specific treatment given for some cutaneous tertiary lesions was the key to the recognition of its real nature.

Echinococcus of the lung also belongs to the rarer diseases, at least in this country. It is much less frequent in France, and in the Argentine Republic or in Australia it is one of the commonest chronic maladies of the chest. Haemoptysis may be the only symptom during the initial period. If the cyst is located in the vicinity of the pleura, it causes a pleural effusion which simulates tuberculous pleurisy. If it has emptied into a bronchus, the signs are those of a lung cavity, and attributed for this reason to tuberculosis, unless one has been fortunate enough to observe the pathognomonic membranes when they were expectorated. The absence of tubercle bacilli in the sputum together with the characteristic ball-like appearance of the cyst on the fluoroscope or the plate, and the specific complement fixation are the only means to come to a correct diagnosis.

Cancer of the lung or bronchi is not so exceptional. The diagnosis is always a difficult one. In a recent paper dealing with the 29 cases of bronchial or pulmonary malignant growth which came during the last twenty years to autopsy at the University Hospital of Geneva, Cramer, Saloz, and Mlle Cottin showed that the clinical diagnosis had been the right one in only 20 per cent. In five instances the mistake was due to an unjustified admission of tuberculosis, based on physical signs of consolidation or cavity, dyspnoea, coughing, wasting and haemoptysis. Almost all the cases of lung cancer which I have observed had been previously regarded as cases of consumption. One must not rely upon the finding of neoplastic cells in the sputum, nor upon their demonstration in the pleural effusions which frequently complicate the new growth. They are seldom to be found under the microscope, and sometimes quite impossible to differentiate from modified endothelial cells. Only careful x-ray examination and the absence of bacilli in the sputum can lead to an accurate diagnosis, if there are no definite arguments such as those which are sometimes to be found in the microscopic examination of a subcutaneous metastatic nodule. Even the demonstration of tubercle bacilli in the sputum is not always to be interpreted against cancer, as one knows cases where a malignant growth has originated on the walls of a tuberculous lung cavity.

Bronchiectasis is a morbid condition more commonly observed than either syphilis, echinococcus, or cancer of the lung. If it were always manifested by the symptoms described in our textbooks, especially by the characteristic and abundant morning discharge of offensive purulent secretion, it would undoubtedly be diagnosed correctly in the majority of cases. But one must remember that, for many years, a bronchiectasis may determine a secretion which is not only non-offensive, but intermittent, periods of apparent inactivity alternating with periods of abundant secretion coinciding with irregular fever. Sudden and profuse haemorrhage as well as light and prolonged expectoration of blood are also a by no means unusual feature of the disease. The physical signs are those of focal consolidation with a central cavitation. The classical axiom that apical cavities are tuberculous, whereas cavities located at the base speak in favour of bronchiectasis, is one of those traditional golden rules which are just approximate enough to be dangerously misleading. As a matter of fact, apical bronchiectases are not more exceptional than basal tuberculous cavities, as pathologists well know. I have recently compiled all the cases of bronchiectasis which came under my observation at the Laennec Hospital since June, 1919. Out of a total of 22, 14 had been mistaken for consumption and treated as such. Some of them had spent years under sanatorium cure. If more stress had been laid on the permanent absence of tubercle bacilli in the sputum,

and if the past history of the patients had been more carefully investigated, I think this proportion of errors could have been very materially reduced. To ascertain, in the anamnesis of a patient who expectorates non-bacillary purulent sputum, that his trouble has begun after he has had a typical pneumonia, or, in childhood, a bronchopneumonia complicating diphtheria, measles, or whooping-cough, is, in my opinion, more important than to verify if his expectoration has the macroscopic aspect so complacently described by our classics. A history of foreign body aspirated into a bronchus should also be searched for.

Purulent non-tuberculous pleurisy, whether located in an interlobar fissure or encysted in some other part of the pleural cavity, is also one of the diseases which may for a long time escape recognition because they are mistaken for tuberculosis. An empyema gives focal signs and general symptoms such as fever and wasting; when ruptured into a bronchus, it determines purulent expectoration. I am sorry to say that these manifestations are deemed quite satisfactory arguments by many a medical man, to label the case "consumption" without any further investigation.

One could easily lengthen the list of pulmonary and pleural conditions which in daily practice one has the opportunity to discriminate from pulmonary tuberculosis. But, at the risk of being blamed for some omission, I hasten to draw your attention to the third class of ailments which are apt to bias our diagnosis—namely, the morbid conditions of the upper respiratory passages. Experience has shown that they are to be considered as a very frequent, if not as the most frequent occasion of error. The common cold—or, to give it its pompous scientific names, acute coryza or acute rhinitis—is a mild infection of the nasal cavities which, as everybody knows, easily spreads to the pharynx, the larynx, the trachea, and the larger bronchi, determining coughing and expectoration. It is a strange fact that one generally overlooks the very plausible probability that chronic infectious conditions of the upper air passages should do the same. Now the labours of our friend, the nose and throat specialist, have taught us that there is quite a variety of those chronic conditions, and that they are exceedingly common: antrum suppurations, for instance, or purulent discharge from the ethmoidal, frontal, or sphenoidal cavities. Adenoids are special to childhood, but they often persist in the adult, as well as hypertrophy of the pharyngeal, lingual, or palatine tonsil. Atrophy of the turbinates is not always associated with its signal symptom, ozaena, but it is always determined by a chronic infection whatever the causal micro-organism may be. More frequent still are those minor abnormalities which are not infectious by nature but which give occasion to benign infectious catarrhs, such as hypertrophied turbinates or deflected septa.

Curiously enough, up to recent times, whenever the possibility of an influence exerted by nasal abnormalities on the deeper respiratory organs was thought of, one always considered this influence as a merely mechanical one. It was generally admitted that nasal obstruction is able to disturb the functional activity of the lung, and, by so doing, to create a predisposition for tuberculosis, or to produce, as in Kroenig's theory, an apical collapse simulating early tuberculosis. Outside of nasal obstruction one could imagine no such influence. The infectious element was entirely ignored. To explain this indifferent attitude of the profession, one must perhaps take into account the indifference with which the patients themselves regard the conditions I have just alluded to, even when they have been subject for years to chronic catarrhal or purulent rhino-pharyngeal discharge. They very often get so accustomed to this ailment that they do not even mention it to the physician whom they consult, complaining only of coughing. And yet their habitual coughing may be nothing else but one of the symptoms of a simple chronic bronchitis due to their chronic nasal catarrh, exactly in the same way as acute simple bronchitis originates from an acute common cold.

Even the nose and throat specialists are often blind to the fact.

"O fortunatos nimium, sua si bona noriat!"

as Virgil said of the labourers in the fields. When one has had one's attention drawn to this connection between infections of the upper respiratory organs and chronic coughs with

occasional signs of disseminated or localized bronchitis, it is quite surprising how often the curetting of an antrum, the withdrawal of an hypertrophied turbinate bone, the removal of adenoids or of hypertrophied tonsils puts an end to a long story of apical catarrh or of suspicious bronchitis or of incipient tuberculosis. Over 50 per cent. of the cases which I reported as non-tuberculous after observation in the diagnostic clearing stations I conducted during and after the war belonged to that class of patients. Since I first published my views on this subject in 1916 they have been confirmed by many physicians, among whom I would like to mention especially Professor Sergeant in France and Dr. Gerald Webb in the United States.

REASONS FOR MISTAKES IN DIAGNOSIS.

There are many reasons to account for the large proportion of mistakes which are committed in the discrimination of lung tuberculosis from other respiratory disease. It is not my intention to mention them all. But I may be allowed to deal briefly with one or two. In the first place, the importance of an early diagnosis of tuberculosis has been urged upon us by our teachers, by public health authorities, and even by public opinion, with such force and persistency, that however beneficial and well meant this urging has been and still is, it has to some extent biased our clinical judgement concerning individual cases. Even that admirable institution, the dispensary, is in many places organized as if the patient who enters it for the first time could not be suffering from any other disease than tuberculosis. The printed forms where the histories, the symptoms, and the results of physical examination are to be consigned, direct unconsciously our thoughts towards one hypothesis only—namely, tuberculosis. And it seems as if the medical officer had only to decide whether the case is one of simple exposure, or of incipient, confirmed, moderately active, progressive, arrested, or healed tuberculosis. If the physician is not a very experienced clinician, using all the diagnostic means at his disposal in a well-equipped institution, if he has not a strong character and an active, investigating mind, he will naturally be inclined to follow the line of least resistance which is so carefully and methodically drawn before him.

In the second place, I should like to say that, in my opinion, too great importance is generally given to symptoms *versus* signs as a positive basis for a diagnosis of tuberculosis. Symptoms have their due place in the mental process which leads to a diagnosis. I am in no way inclined to minimize their value, which is great. They are the indispensable starting point of our journey. But one is too apt to forget that the journey is quite as indispensable. As a matter of fact there is not a single symptom, not even a single association of symptoms, which tuberculosis has not in common with other diseases. Loss of appetite, weight, or strength, shortness of breath, coughing, expectoration, fever—all belong to an extraordinarily large group of morbid conditions. Even the so-called pathognomonic subfebrile temperatures after exertion are commonly observed in all sorts of chronic or subacute, more or less latent infection (chronic appendicitis, for instance, or an inflamed Fallopian tube, or a suppurating antrum). Nor is it always absent in conditions which are not infectious at all, as in Graves's disease. Haemoptysis is very generally considered as an almost infallible positive sign of tuberculosis, and yet we know that it occurs in every focal non-tuberculous disease of the lung: syphilis, cancer, bronchiectasis, gangrene and abscess of the lung, and echinococcus have this characteristic sign in common with tuberculosis. We also know its diagnostic value in mitral stenosis and in malignant endocarditis, not to speak of the sometimes very profuse haemorrhages which signalize papillomatous or epitheliomatous new growths of the larynx or varicose veins in the trachea or the pharynx.

The first step after analysing the symptoms is to look for positive signs of a localized lung lesion. And here begins properly the task of the physician. Percussion, auscultation, and the other methods of physical examination must be applied without any bias. I mean that the physician should not, at this step, ask himself the question: Has this patient tuberculosis? But simply: Is there, either in the lung or elsewhere, a localized lesion which may account for the symptoms observed? I need not emphasize again the value of an x-ray examination of the chest, to show whether such a lesion can be demonstrated or not. If it cannot be demonstrated in the lung, then let us look for it in some other part of the body. And here, after due

consideration of the cardio-vascular and other systems, comes in the careful examination of the upper air passages by an expert. It will often, I dare say, prove fruitful of a correct diagnosis.

On the contrary, if the signs of a localized lesion—or of several localized lesions—are found in the lung, if the gross anatomic characteristics of this lesion have been ascertained by an x-ray investigation, we may proceed to diagnose the specific nature of the lesion, by using the tests which are at our disposal for that purpose. As regards tuberculosis, there is only one positive test—namely, the finding of tubercle bacilli in the sputum. It must be used with a persevering tenacity. One negative result means nothing. I would not like to give a limit to the number of examinations which are necessary. But I think ten negative results mean a lot, if the search for bacilli has been prolonged, if the sputum has been homogenized, and if animal inoculation has not been neglected. May I add that one positive result may mean very little? There are stupid, but not always quite unavoidable, causes of error, which every trained laboratory worker knows, and there may be also intentional deceit from the part of the patient, if he is eager to get an undeserved pension or compensation.

It would be absurd to contend that the diagnosis of tuberculosis is justified only when bacilli have been demonstrated in the sputum. But the more one studies this question of the discrimination of tuberculosis from other disease, and the more one has opportunities to follow up patients for long periods of time, the more one sees how very frequent indeed are the cases, even the quite early cases, of real tuberculosis where bacilli are found in the sputum, when they are carefully looked for. I do not mean to say that a patient with positive signs of a localized lung lesion and no demonstrable bacilli is certainly not tuberculous. I say that our duty in the absence of bacilli, is to endeavour earnestly to ascertain whether some disease other than tuberculosis may not account for the symptoms and signs observed. Only if we do not succeed in our investigation are we entitled to admit the diagnosis of tuberculosis, so to say, by exclusion and as the most practical working hypothesis.

DISCUSSION.

Dr. MARCUS PATERSON (Colindale Hospital, Heudon) said: I have two criticisms to make on Professor Rist's paper, otherwise I am in agreement with his remarks. In the first place, he told us how to establish the existence of tuberculosis but did not suggest any method of determining whether the disease in a non-febrile patient is active or not. He states that "new and important knowledge has slowly been gained on this point, but we have failed in adapting our diagnostic procedure to this knowledge." He does not appear to realize that we have now the auto-inoculation test, which, especially if pressed to the point of reaction in a case with positive sputum, is of great value. Certain symptoms which give good warning are shown by a patient when the reaction is approaching—namely, in the following order: insomnia, anorexia, slight malaise, and marked deviations in temperature. The more certain one is that the case is not tuberculous, the more the test can be pressed. Then, again, there is the complement fixation test to prove infection. To some extent this test also indicates activity.

I agree with him, from my experience at Colindale, that a mild first infection confers immunity. I do not know if any facts bearing on this have yet been published, but I have, at the request of Sir James Kingston Fowler, been keeping records of signs of previous tuberculous disease—for example, scars of operation on glands, etc.—in patients suffering from advanced tuberculosis admitted to Colindale Hospital, and under 5 per cent. bear such evidence.

The generally accepted statement that persons dying of tuberculosis have evidence of old lesions in the abdominal glands has been tested in some two hundred necropsies, and is found to be quite untrue. Tuberculous glands are present in only a very few cases. I do not deny that they may be present in patients dying of other affections, but they are very uncommon in persons who have died of pulmonary tuberculosis.

I should like to quote some figures to indicate the necessity of repeated examination of sputum when the first examination is negative. These results refer to sputum passed by a medical officer as such, and not simply saliva sent by the patient. Excluding cases which had abundant bacilli on

the first two examinations, and also cases which are negative up to ten examinations or more, and taking only those sputa from patients with very extensive signs we find, after careful search, that two out of three examinations are negative. In this advanced type of case it was also found that specimens which had not been passed in the first place by the medical officer as actually sputum gave a very large percentage of negative results. Professor Rist says that one positive sputum means very little—I would say it means nothing. To illustrate my meaning I might, if time permitted, quote in full six cases who died and in whom there was no macroscopic evidence *post mortem* of any pulmonary tuberculosis whatever. In all of these cases a positive sputum had been returned. I would suggest, therefore, that there must be many similar mistakes, as it must be a rare thing for a man not suffering from pulmonary tuberculosis to die in a tuberculosis institution. For the six cases mentioned there are, therefore, probably many hundreds who have thus been labelled tuberculosis and who do not die of it at all. The greatest care should be taken in sending specimens to a laboratory not to mix names. It is obvious, therefore, that a positive sputum should always be confirmed before a man is labelled tuberculosis. All the above six cases had been through several institutions and treated at great cost. It often happens that a man once labelled tuberculosis is never allowed to have any other illness. In one of these cases the radiologist reported that there was definite and active tuberculosis in the lung.

Professor S. LYLE CUMMINS (Cardiff) said: It is a great pleasure to hear from the lips of such an authority as Dr. Rist this frank admission of the difficulties that exist in what is often thought a relatively simple diagnostic problem. To me it is a source of particular interest and satisfaction because it has been urged by several critics of the new Diploma of Tuberculosis which we have started in Wales that it is quite unnecessary to attempt to produce specialists in connexion with a disease which is so well comprehended by the average doctor. Those who agree with Dr. Rist will readily admit that without very special training and experience, and without access to the aids to diagnosis afforded by good radiology and good laboratory facilities, even the very capable and careful medical man may easily become involved in serious error. The remedy lies in closer study of modern methods and in the taking of special courses of instruction in tuberculosis; and it was with the idea of encouraging those likely to have to deal with tuberculosis to take such courses that the tuberculous diseases diploma was initiated. There is one readily accessible clinical aid to diagnosis of which Dr. Rist has made no mention, but I think it of sufficient importance to deserve special consideration; I refer to the application of Dreyer's physical standards to routine examination of cases suspected of pulmonary tuberculosis. The use of the spirometer is not as general as it should be, and its use, combined with the recording of trunk length, chest measurement, and weight, with the aid of Dreyer's tables, need only be tried to be appreciated. As an index of the progress of cases it is, too, of great value. Evidence for the applicability of these standards to tuberculosis of the lungs will be found in the paper by Dreyer and Burrell, and a more recent communication by Cameron. My own experience with those standards, though the cases do not yet amount to a sufficient number to justify publication, is most favourable.

Perhaps because of the limitations of his title to the clinical differentiation of the disease, Dr. Rist has omitted all mention of serological reactions as aids to diagnosis. The great difficulty about these tests lies in the fact, to which Dr. Rist has so effectively called attention, that we have to bear in mind the practical difference between infection and disease. The aim of the physician is to diagnose disease, not merely to detect infection; and serological tests share with the tuberculin tests the disadvantage that they are liable to be too delicate for this purpose, giving a positive response in a good many cases of infection that may never reach the stage of actual disease. Still recent reports on the complement deviation test give reason to hope for great help in the diagnosis of active tuberculosis by its means. It is the fashion of the moment to regard the opsonic index of Wright as of no account, chiefly, I think, because the test is too difficult for the busy practitioner and too uncertain in its results to appeal to the laboratory worker. Its uncertainty upon the numerous factors that underlie it. These factors are very little understood, but they are worth studying.

For a disease in which the amount of infection is of such paramount importance the fact that the opsonic index gives a quantitative expression of one of the responses to infection gives it a claim to consideration. Where the test has been carefully applied it has given interesting results, notably in the hands of Dr. Marcus Paterson. I have been engaged for the past two years in re-examining the factors underlying this test, and I have to admit that they are very obscure. I am convinced, however, that the test, in the form originally devised by Wright, is of very definite value, and I would urge those workers in well-equipped sanatoriums with clinical laboratories at their disposal to reconsider it if only to the extent of accumulating records by which its value in differential diagnosis may be finally judged.

Dr. IAN STRUTHGAS STEWART (Nordsrach-on-Dec, Banffshire) said: I have listened with much interest and appreciation to Dr. Rist's paper and am in entire agreement with him that it is essential for the physician dealing with the treatment of tuberculous patients to have a thorough knowledge of the use of x rays for the purposes of diagnosis. It would appear to me that at present there is a tendency to place too much reliance on the negative or print and to neglect the radio-scope examination. It may also be that we are apt to read too much into the lights and shadows of the radiogram, as, after all we are only dealing with varying intensities of light, and many things cause shadows in the lung tissue other than tuberculosis. Then, again, I do not consider it possible in the majority of cases to differentiate by x rays alone between active and quiescent tuberculous disease. That disease of the upper air passages has a profound effect on disease of the lungs I consider to be amply proved. This is frequently to be observed in cases of pulmonary tubercle who develop a simple nasal catarrh, accompanied by an increased intensity of the physical signs in the lungs. That haemoptysis is not always symptomatic of tuberculosis of the lungs is shown by the frequency with which this symptom is met following trauma of the chest wall. In many such cases no symptoms or signs of tuberculosis could be found, and the subsequent history has proved the accuracy of the diagnosis. These cases are of special interest to the pensious medical officers. The question of diagnosis between active and quiescent disease often necessitates the continued observation of the patient for a week or more, and resolves itself largely into the question of whether toxæmia is present or not, irrespective of the intensity or extent of the physical signs. Sarcoma or endothelioma of the lung may simulate pulmonary tuberculosis both as regards the character and the distribution of the physical signs. The presence of a bilateral pleural effusion should raise the suspicion of malignant disease in the thorax.

Dr. JAMES CROCKET (Lecturer on Tuberculosis, University of Glasgow) said: I appreciate Dr. Rist's paper, but feel that there is another side to the picture. Undoubtedly many cases are diagnosed as tuberculous that do not suffer from that disease. Many more are diagnosed and treated for other conditions who actually suffer from pulmonary tuberculosis. Out of 1,100 cases that had been under treatment at Bridge of Weir Sanatorium during the past three or four years 168 had been discharged as "not improved." The majority of these cases are by this time dead. Investigating the history of those patients I find that only 31 had been known to be suffering from pulmonary tuberculosis previous to admission. The remaining 137 cases had been under treatment for from one to fifteen years for other conditions, particularly bronchitis, influenza, anaemia, laryngitis, rheumatism, and neurasthenia. That they had suffered from phthisis during this period there is little doubt. To miss tuberculosis when it is present is, in my opinion, a much more serious thing for the patient than to diagnose tuberculosis and treat the patient for that when it is not there. Sputum examination is not to be depended upon in diagnosis. Out of 2,204 cases tubercle bacilli were only found on the first examination in 60.9 per cent. Patients at present in residence whose sputum has been examined give interesting figures. One examined fifty-seven times, only showed tubercle bacilli on five occasions; another, forty-three times, on four occasions; another, twenty-seven times, on two occasions. One patient previously in the sanatorium, with numerous tubercle bacilli in the sputum, was readmitted recently on account of an exacerbation of the disease. Her sputum has been examined since readmission fifteen times with a negative result. The von Pirquet test has been found far from satisfactory, and in

my experience is not a very sensitive test. Out of 700 undoubtedly tuberculous cases positive results were only got in 80 per cent. of the cases. The complement fixation test has been used, but with rather disappointing results. Dealing with several hundred cases I got 90.5 per cent. positive; 9.5 per cent. undoubtedly tuberculous cases gave negative results. As controls the bloods of 67 epileptic patients were examined, and of that number 12 per cent. were positive. I do not object to 9 per cent. of the tuberculous cases giving a negative reaction, but do not like 12 per cent. of the control cases, undoubtedly not having clinical or obvious tuberculosis, giving a positive reaction.

Dr. A. FERGUS HEWAT (Edinburgh) said: Personally I have found Professor Rist's paper most useful in giving clear lines to this vital question of differential diagnosis. My interest in this question of differential diagnosis as it affects soldiers and pensioners began while in charge of fifty beds for tuberculous cases in the army, and has been continued among pensioners sent to the special hospital arranged by the Ministry of Pensions, on the advice of Sir Robert Philip, for such cases. The problem we have to face amongst such patients is not the old well-discussed question of early diagnosis, but rather the correct valuation of symptoms, signs, and other phenomena which have gone on for months—in many cases years. As one writer puts it: "It is the grouping of the elements rather than the mere presence or absence of elements."

It may be of some interest to members of this Section if I give a few figures from Kingscroft Ministry of Pensions Hospital for 1921. In that year 144 cases were admitted. Practically all of them suffered from pulmonary symptoms which caused them to be referred to this hospital. In 66 of these cases a definite statement was made on their admission form that pulmonary tuberculosis was suspected. This tentative diagnosis had been formed after repeated medical examinations. In 42 of these cases I felt justified in confirming the tentative finding; in 10 of these confirmation was made certain by the presence of tubercle bacilli in the sputum. The remaining 32 included cases classified as chronic pulmonary tuberculosis with bronchitis and emphysema, a case of glands in the neck, and a tuberculous hip. Most of the cases were very chronic in type, and the associated chronic bronchitis and emphysema was the obvious crippling disability and the label under which the patient was in receipt of pension. Fifteen other cases in which the tentative diagnosis of tubercle had not been specifically stated—although probably suspected—I felt justified in classing as chronic pulmonary tuberculosis; in two of these the sputum was positive. The others were of the old-standing type, with chronic bronchitis and emphysema, several of which had been admitted with a diagnosis of asthma. In dealing with these cases I find that one of our most-valuable elements in framing a diagnosis is absent. I refer to the history of the illness, on which most of us look for a third of our evidence. I have yet to find the pensioner who is willing to give a clear statement as to symptoms of illness before he joined the army! I am glad to hear Professor Rist insisting on the frequent examination of the sputum. One would have expected to find this elementary point had long ago been clearly grasped, but in my experience this is not so. I have had cases in the army and among pensioners where the value of arduous search has been amply proved. In one case tubercle bacilli were found on the thirtieth consecutive examination, in another on the twenty-eighth, in another on the eighteenth, in another on the fourteenth, and so on. Tubercle bacilli at times come in showers, and these are liable to be missed. Laureston-Brown's remark on this subject is worthy of citation: "Failure to find and interpret aright physical signs may be excused, but failure to ask for and examine sputum cannot be condoned." It is unfortunately difficult in this country to make free use of guinea-pig inoculation in diagnosis. The next question I found of interest in dealing with this group of cases is the reasons why cases are suspected of being tuberculous. They divide themselves roughly into three main groups as regards these pensioners, as follows: Group 1, Cases showing well-marked local pulmonary symptoms, with bronchial physical signs in excess of pleural or lung tissue signs. Group 2, Cases showing well-marked chest physical signs of a local nature, the symptoms (local or general) being not unduly prominent. Group 3, Haemorrhage cases—that is, patients who state that they have expectorated blood.

In the first group one finds "gassed" cases, or, more

strictly, pensioners who state that they have been gassed and show symptoms and signs of chronic bronchitis and emphysema in varying degree. At times such cases are rather a puzzle, for various reasons. In the first place, the history is of practically no value, and one has found little help from medical literature in relation to the late effects of gas poisoning. Secondly, we know that warfar gas caused the lighting up of some cases of tuberculosis, but, as French and American authorities have pointed out, not nearly so frequently as one might at first suppose. Thirdly, x rays have demonstrated a peribronchial fibrosis with hilus enlargement in many "gassed" cases, and the plate or report is frequently returned with the label, "peribronchial tuberculosis." Fourthly, as a consequence of gassing, cough is induced, giving rise to further development of chronic bronchitis and emphysema, a lesion commonly associated with a fundamental tuberculous process. A short paper by John B. Hawes of Boston points out how gassing induces irritative and escharotic effects on the respiratory tract, and the healing process is found to induce scar tissue, contraction, and mechanical defects. This naturally leads to a proliferative fibrosis which destroys the natural protective properties of the bronchi and leads to secondary infection, in which he says tuberculosis plays a minor part. In these cases shortness of breath and nervous phenomena are prominent features. Many such cases are classified as D.A.H. The prolonged duration of symptoms in the absence of toxic phenomena go far to establishing a non-tuberculous diagnosis in these cases. The patient, not his lungs, requires treatment.

In the second group one finds two subdivisions. (a) Gunshot wounds of the chest, where there has been resulting deformity and fibrosis. It is common knowledge that there have been fewer cases of active tuberculosis following wounds of the chest than one might have supposed. I have only had three cases in which tubercle bacilli were isolated from the sputum. Most of the gunshot wound cases have lacked the element of systemic intoxication, and only showed mild local symptoms despite well-defined chronic physical signs of a localized type. (b) This subdivision includes the old boggy of failure to appreciate the normal exaggeration of physical signs at the right apical region. That this is still a trap for the unwary we have on the excellent authority of Sir James Kingston Fowler, who says in his recent book on pulmonary tuberculosis: "We desire to mention that we have been in the habit of revealing to students the fact that a modest competency may be realized by correcting the errors of those who find the right apex seriously diseased when it is quite normal."

In the third group I find a few cases giving a history of haemoptysis which at times is misleading. Some patients in this group are distorters of the truth, and others interpret a mere streaking of sputum with blood as a frank haemorrhage. Careful cross-questioning as to the type and duration of the haemorrhage, also its relation to severity of coughing, usually elicits sufficient information to estimate this symptom at its true valuation.

The differential diagnosis of pulmonary disease is essentially the field for the skilled physician who can sift all the evidence available from physical examination, x ray findings, bacteriologists' findings, etc. Apart from tubercle bacilli in the sputum, there is no certain sign of pulmonary tuberculosis, and it is only by the correct valuation of all points that reasonable accuracy can be obtained. We should be able to diagnose our cases, and not merely say such a one is not tuberculous.

Dr. JAMES LAWSON (Tor-na-Dee) said: From the point of view of a doctor dealing entirely with patients who are already in a sanatorium the question of the differential diagnosis of pulmonary tuberculosis becomes somewhat limited, but there must always be, I venture to think, in every sanatorium a number of cases in which, although there is evidence to lead to the suspicion of tuberculosis, a definite diagnosis has not been made. In an endeavour to reduce the number of such "uncertain" cases I wish to direct your attention for a moment to a condition first described by Castellani in 1905, and which has not received adequate recognition and investigation in this country. I refer to the condition known as broncho-pulmonary spirochaetosis. Cases have been described in Switzerland, France, and Italy, but so far as I have been able to trace them only four cases have been published as occurring in this country, and of these two were without possible connexion with the tropics. To these

I might add a case at present, under our own observation at Tor-na-Dee Sanatorium—a lady, who has never been out of this country.

As described by Castellani, there appear to be two types of disease—an acute and a chronic form; both are liable to be mistaken for pulmonary tuberculosis, but it is especially the chronic form that I would direct your attention, as all the cases so far described in this country fall into this category. Males appear to be more frequently affected than females, and the age incidence tends to be over 30. There may be a history of a febrile attack at the commencement of the illness, but for the most part cases are afebrile. If fever is present, Castellani considers it more usual that it should be of the inverse type. Cough with expectoration is present and haemoptysis has occurred in every case as yet described—this may vary from mere staining of the sputum to a frank haemoptysis. The physical signs in the lungs may be negative, or more usually those of bronchitis, but consolidation may also be present. The general condition of the patient is rarely affected to any extent. The sputum cannot be shown to contain tubercle bacilli, but always swarms with spirochaetes whose morphological characteristics, as Castellani pointed out, vary widely even in the same case. The clinical picture is one which could easily be accepted for pulmonary tuberculosis, but the cases tend to diverge from the ordinary case of pulmonary tuberculosis in the following ways: (1) Absence of tubercle bacilli in the sputum. In the case which we have under observation no tubercle bacilli have been found, although each twenty-four hours' sputum for the past two months has been subjected to the concentration method of examination. (2) Enormous numbers of spirochaetes are always present in the sputum. (3) There is an almost entire absence of systemic disturbance. X-ray photographs do not show the usual shadows found at apices and further reveal no positive evidences. (4) In the case we have under observation the sputum presents certain peculiarities. It is thin and watery, containing greyish-green mucoid material, which has been likened to gooseberry juice. But the most characteristic feature is a peculiarly nauseating, penetrating, acid odour, which becomes greatly intensified when the sputum has been allowed to stand for some time. The odour is quite distinctive. I know of nothing which it resembles.

The question which naturally arises at once in this connexion is whether this condition of broncho-pulmonary spirochaetosis is a pathological entity or whether it is merely a superadded spirochaetal infection to a tuberculous lesion. The absence of the tubercle bacillus does not negative the diagnosis of tuberculosis, and the presence of the spirochaete in tuberculous sputum is well known, but in these cases its probable origin is in oral lesions. Most of the cases of broncho-pulmonary spirochaetosis show oral lesions, but in the case under our care, even after efficient dental treatment and treatment of the gums, the sputum, collected with all possible precautions, showed no diminution in the number of spirochaetes. So far as I know, only one post-mortem examination has been reported with the idea of distinguishing any pathological change in the lung as the result of a spirochaetal infection, but as the patient also suffered from pulmonary tuberculosis, syphilis, and malaria no conclusion can, I think, be drawn from the findings. I feel that there can be no doubt that broncho-pulmonary spirochaetosis is clamouring for recognition as a separate disease, although further investigation is necessary to settle the question definitely. I hesitate to suggest what proportion of undiagnosed or wrongly diagnosed cases should be included under the label "spirochaetosis," and, although not large, I think they would be appreciable. As prognostic, therapeutic, and administrative considerations rest on the recognition of the condition, I consider that it should be given a more conspicuous place in the differential diagnosis of pulmonary tuberculosis.

Dr. C. MUTHU (Mendip Hills Sanatorium) said: The differential diagnosis of pulmonary tuberculosis presents many difficulties even to expert observers, because it has a wide relation to many diseased conditions, its symptoms and signs closely resemble those of many other respiratory affections, and because its physical evidence varies in different individuals, there being no recognized standard of physical signs common to all cases of pulmonary tuberculosis. While it is true, as Professor Rist has pointed out, that many cases are wrongly diagnosed as pulmonary tuberculosis, it is also much more true that a positive diagnosis is more often missed than

wrongly made. I quite agree with Dr. Pottinger, of America, when he said that we are missing tuberculosis ten times more often than we are diagnosing other diseases as tuberculosis. One reason is that a large number of phthisical cases do not go farther than the incipient stage and get well of their fever, cough, sputum, etc., after a change and rest in the country, leaving behind a certain amount of impaired resonance and harsh breathing. In the diagnosis of pulmonary tuberculosis we come to deal with three sets of evidence—the presence of tubercle bacilli, physical signs, and symptoms. When tubercle bacilli are present in the sputum the diagnosis is positive in many cases. But we have this curious fact that in some cases tubercle bacilli may be found in the sputum and yet the patient may not be tuberculous. This may be due to the difficulty of differentiating between tubercle bacilli and the acid-fast rods getting into the sputum from milk, butter, the soil, manure, saliva, and even from water. On the other hand negative sputum does not indicate the absence of tuberculosis. In many cases with well-recognized signs and symptoms of phthisis tubercle bacilli cannot be demonstrated even after careful and repeated examination. Further, as tubercle bacilli make their appearance only after the lung breaks down their evidence does not help in the diagnosis of early cases or in those cases which remain in the incipient stage for months and even years. So more important than the presence of tubercle bacilli is the evidence of physical signs, especially auscultation. A wary, jerky, and harsh breathing, crackling or crepitant râles heard at the end of inspiration, especially following a cough and confined to the apex or apices, ought to make the diagnosis certain. The more we depend upon laboratory evidence the more auscultation is apt to be neglected and the more it fails to help in the diagnosis. Only life can interpret life. The living ear of the physician can detect and interpret correctly the various shades of breath sounds when the dead physical helps are unable to give a decided diagnosis.

Sometimes even physical signs may fail. I have seen cases, especially in India, where nothing but a high temperature and rapid pulse and sometimes enlarged glands mark the course of pulmonary tuberculosis for many weeks with vague or no physical signs. These cases may take an acute galloping form or end fatally from general toxæmia. I call attention to this Indian type as it is apt to be mistaken for malarial and other fevers. Also in some chronic and afebrile cases physical signs may be very obscure. So more important than physical signs are the evidence of symptoms, such as a slight but persistent rise in temperature, rapid pulse, mild but constant cough, loss of weight, languor and tired feeling, anaemia, dyspnoea on exertion, anorexia, symptoms of dyspepsia, slight haemoptysis, etc. If these characteristic symptoms, when present, are carefully studied and valued with due regard to perspective, they can be relied on to yield a fairly accurate diagnosis of early tuberculosis even if tubercle bacilli are not found in the sputum. It is possible that almost all these symptoms, as Professor Rist and others have shown, may be shared by many respiratory diseases such as acute bronchitis, bronchiectasis, subacute lobar pneumonia, acute colds and influenza, apical catarrh, etc. Most non-tuberculous cases occur in the middle or lower lobe of the lung, and constitutional symptoms, such as temperature, quick pulse, loss of weight and strength, are not so severe or progressive as in tuberculosis. But differential diagnosis becomes very difficult in apical and localized bronchitis and bronchiectasis, in unresolved pneumonia where acute symptoms continue more or less indefinitely, in influenza pneumonia, and other pulmonary focal infections. Many a case of so-called influenza is but an acute attack of latent tuberculosis; and bronchopneumonia and lobar pneumonia may be the beginning of acute pulmonary tuberculosis. In one of my sanatorium cases pneumococci were present in the sputum for several months and were gradually replaced by tubercle bacilli. These cases, presenting almost all the signs and symptoms of phthisis, may be the forerunners if not identical with pulmonary tuberculosis. Especially, apical catarrh and collapse induration of the apex in strumous children brought up in poor surroundings and insufficient food, cases which Bard and Fishberg call "abortive tuberculosis," cases of hyperthyroidism with lung complication, in all of which well-marked signs and symptoms (such as fever, rapid pulse, dullness of apex, impaired movement, dry and moist râles, cough and expectoration, and even slight haemoptysis) very closely simulate those of early phthisis, should to my mind be classified as incipient or benign form of tuberculosis. In fact, I plead that our ideas

and interpretation of pulmonary tuberculosis should be widened and not be confined only to cases which present a positive evidence of tubercle bacilli, and that all cases where differential diagnosis is difficult and impossible, requiring time and observation, should be sent to sanatoriums which should be observation centres and for early treatment. In this way we give the patient the benefit of the doubt and ensure speedy recovery, and thus save time, trouble, and expense both to his family and to the State. I cannot help suspecting that at least some of the so-called non-tuberculous cases—of course excluding all other possible causes—are obscure and ill-defined forms of tuberculosis or cases that stop at the incipient stage and get well after a few weeks' treatment. The family physician is faced with this dilemma: if he sends early cases for treatment before tubercle bacilli appear in the sputum he may be told that it is a non-tuberculous case; and if he waits for the appearance of the bacilli he risks the patient's life and makes the chances of his recovery uncertain. But the fact already mentioned, that more cases of phthisis are overlooked than mistaken, should help to sink the scale for early diagnosis and treatment, even though tubercle bacilli cannot be demonstrated in the sputum.

Dr. A. HOPE GOSSE (London) confined his remarks to the evidence on which Dr. A. Lisle Punch and he claimed that, with a method (described by his colleague) of doing the complement fixation test, they had an almost infallible guide as to the presence or not of active tuberculosis. The blood of the patients with tubercle bacilli in their sputa were positive in 98 per cent. of cases. Control tests, with serums from cases without clinical evidence of active tuberculosis, were negative in 98 per cent. Fifty Brompton Hospital patients, suspected of the disease until the test was done and found to be negative, were still free from any development attributed to tuberculosis in 49 of the cases some ten to twenty months later. Likewise in a series of 50 consecutive suspicious cases, in which tubercle bacilli had never been found when they gave a positive test, of those able to attend between a year and two years afterwards 45 per cent. had tubercle bacilli in their sputa. With the assistance of this test a confident diagnosis of pulmonary tuberculosis had been made in one of these cases two years before tubercle bacilli had been found in the sputum. Their experience showed that the test was almost always positive by the time the symptoms due to the infection had developed. The blood still gave a positive test for perhaps about a year after the disease was arrested. It had been authoritatively stated that early diagnosis was the most important factor in the prognosis of the disease, and it was therefore with a full sense of their responsibility that they announced that in the test, performed by the method referred to, there was now an almost infallible guide as to the presence or absence of active tuberculosis.

Dr. SINCLAIR GILLIES (Lecturer on Clinical Medicine, University of Sydney) thought that the tendency of the meeting was to rely too much on physical signs and tests. What, he asked, was the distinction between "infection" and "disease"? Was it not evidence of toxæmia, and did not diagnosis depend on correlating physical signs and tests with such evidence rather than on placing reliance on any one test or sign?

Dr. EDWARD PREST (Ayrshire Sanatorium) said that they must remember that medical superintendents of sanatoriums spent their time considering for what length of time patients were kept from any kind of effective treatment. Diagnosis was largely a question of symptoms. X rays would not tell whether the disease was tuberculosis, and whether it was active or not. To wait for a positive sputum might be to wait too long. In times of war it was often difficult to rely altogether on a patient's own statements regarding the state of his health. The condition must be diagnosed from symptoms, and in a suspected case other diseases must be excluded, and appropriate treatment then applied. If patients had no symptoms, it would not be necessary to give treatment, but if symptoms were present they should be treated at once. Physicians who were called upon to diagnose and report on suspected cases of tuberculosis should always endeavour to give some explanation of what "negative" patients were suffering from.

Dr. A. S. M. MACGREGOR (Glasgow) referred to the x-ray demonstration which had been arranged by Dr. Henderson and himself in connexion with the discussion on diagnosis.

In this demonstration a set of one hundred films illustrative of different lesions in the lung were shown. From the point of view of difficulties, both in clinical and radiological diagnosis, a special inquiry had been going on in Glasgow in connexion with the large group of cases of fibrotic lesions in the lung, and the demonstration showed instances of peribronchial fibrosis following pneumonia and other acute or subacute lesions of the lung, and also silicosis and other affections.

[A series of films was also shown illustrating the difficulty of determining what is to be regarded as a normal x-ray photograph.]

THE SHARE OF THE SUN IN THE PREVENTION AND TREATMENT OF TUBERCULOSIS.

BY

A. ROLLIER, M.D.,

Loosin, Switzerland.

I wish in the first place to express my thanks to your President, Sir Robert Philip, for the honour he has done me in asking me to come to your meeting in Glasgow. I have come here as the representative of a belief to which I have devoted my whole life, and which is that the sun is the source of life not only for the healthy but also for the sick, and that it should be expected to become an important weapon in the therapeutical arsenal against tuberculosis.

I am particularly happy to give this demonstration under the patronage of such a well-known authority as that of Sir Robert Philip, who was one of the first to organize the preventive measures against tuberculosis in this country. It is a great pleasure for me to know that in your country the value of light and sun has been officially recognized, so that a committee on the action of sunlight has been appointed lately for a scientific study of this question including such eminent men as Sir William Bayliss and Professor Leonard Hill. Let me remind you that this committee has been appointed owing to Dr. Saleeby's very courageous and disinterested campaign for a better hygiene of the towns, the suppression of smoke, and the triumph of light. I am also well aware that sun and light not only are studied in your country, but that heliotherapy has been applied for many years and with well-known success by men like Sir Henry Gauvain in the admirable institution at Alton, by Dr. Pugh at Carshalton, and perhaps by many others who may be here and whom I do not know.

The awakening interest in heliotherapy throughout all medical circles in the world is not only due to the general recognition of the value of a method based upon a more accurate apprehension of the nature of tuberculosis, but perhaps more certainly on account of its special value, the fight against tuberculosis being primarily a social question. The terrible havoc wrought recently in almost every country by tuberculosis has aroused a more widespread interest in this burning question. All that tends to the elimination of this scourge is of supreme importance. Internal and external tuberculosis are not only local ailments requiring local treatment, they must be regarded as being the seat of a general infection. In dealing with such a general infection, showing local symptoms and appearing in local seats of disease, a therapy giving a general effect must be employed in order to restore the normal constitutional condition of the individual, together with a local treatment which, to be rational, must never and in no way interfere with the necessary rebuilding of the whole system. It was to this end that, in 1903, we opened the first clinic for air-cure combined with systematic heliotherapy at a high altitude, in Leysin, a village of the Swiss Alps (4,500 feet above sea-level).

Open-air life, so eminently reconstructive, associated with complete sun baths, such as we have advocated it since the beginning of our work—that is to say, the direct action of the sun over the entire surface of the teguments—constitutes the most energetic of excitants and tonics. At the same time heliotherapy realizes the rational local treatment, adding to its reconstructive action on the body the analgesic, bactericidal, sclerogenous, and reductive effect of the solar radiations. Sun cure may be carried out wherever the sun shines—on sea-level, by the seaside, on the mountain. If we have chosen the high mountain in which to erect our clinics it is because the alpine air and sun bath may be there taken during each month of the year, thus permitting uninterrupted cure, maintaining the body at its maximum vitality and power of defence.

Action of Solar Rays.

How does the sun act upon the organism? That is one of the most captivating questions, a clear statement of which could be but imperfectly outlined even in a long lecture. Our limited time only allows us to take a very rapid survey of this part of our subject. We should first remember the double action of light on the organism—its direct and indirect action. The direct action has been doubted for long, because the bactericidal violet and ultra-violet rays have only a superficial action. Wiesner's work has, however, proved that the infra-red rays, especially those nearer the red, are also bactericidal, and by their long wave-length can penetrate the organism and thus might have an action on deep-seated lesions. But if the direct action of the sun is still matter for discussion, the capital part it plays indirectly has been proved by numerous experiences which we can only sum up very briefly. Everyone knows that the violet and ultra-violet rays, detained at a depth of one millimetre in the skin, are absorbed by the superficial sanguine surface formed by the net of the capillaries now dilated by the sun. To these rays must be attributed the phenomena of erythema and pigmentation.

Pigment is not only a protective agent against too violent an irritation by ultra-violet rays, but it also regularizes the thermic share of the sun. The profound biological value of pigment is everywhere better recognized. It is very likely that pigment receives, supplies, and increases the activity of the elements essential to the metabolism of the hormones. You know that Bloch has demonstrated that a substance, chemically very much like adrenaline, submitted to the action of oxidized ferments of the epiderm produces the formation of normal epidermic pigments, light strongly accentuating this formation. On the other hand, the skin's ferments seem to depend upon the quantity of vitamin contained in the food, as has been recently proved by the experiment made in Vienna on rickety and insufficiently fed children. Let us also remember that recent German and American publications have demonstrated that the action of radiations produce a very strong retention—which can reach as far as 400 per cent.—of the phosphates and lime in the organism. Let us remember, finally, that Naegeli has proved the action of sun on the haematopoietic system to be followed by an increase in haemoglobin, that Behring has ascertained the more active respiration of the red globules submitted to the sun, and that Schläpfer has given the proof of the photo-activity of a photograph plate, by means of previously insulated blood. Lastly, we might mention the recent experiences of Sonno in Copenhagen, who has proved that under the action of radiations the temperature of the blood, at a depth of more than one-third of an inch in the skin, augments to about 5° C.

From these experiences must be drawn the conclusions that the light absorbed by blood changes it into a receptacle of radiant energy. Transferred into the whole organism this energy hastens the intracellular processes of oxidation and reduction, thus modifying the whole metabolism. Consequently in this way the defence of the organism exposed to the beneficent action of the sun is progressively increased, making it better fit for the fight against tuberculous infection.

The Skin.

Among the general effects of the sun on the body we would first mention its action on the skin. My reason is that we attribute in our results a capital importance to the remaking of this essential organ through the working of the sun. The skin is not only the natural clothing of the body, wonderfully fitted to protect it against the penetration of pathogenic organisms. Provided as it is with a compact web of capillary vessels, it forms a real expansion of the vascular system. These vessels, by their contraction and dilatation, constitute a kind of "peripheric heart"—an admirable regulator of the circulation of the blood. The skin is also an expansion of the nervous system; this close-woven net of sensory and sensitive nerves may be compared to a keyboard, on which all exterior impressions provoke resonances in the whole organism. The skin is not only an organ of protection, circulation, innervation, but also one of respiration and nutrition, since it gives off the carbonic acid and water vapour and absorbs oxygen. Finally, the skin constitutes also an essential organ of elimination; for this reason it has been called the "vicar of the kidney"—perhaps even more important than his superior, for one can easily live having one kidney left, whereas it suffices that one-third of the cutaneous surface should be destroyed through burns to cause death.

These important physiological functions can only be accomplished if the skin is placed in its natural surroundings, and

its natural surroundings are the permanent contact with air and light, just as water is the natural element for the scale of a fish. Weakened and atrophied for many generations through the wearing of unhygienic clothing, the skin, under the action of air and sun, recovers its many and vital functions, and becomes the ideal clothing foreseen by Nature. Gradual formation of pigmentation on the teguments gives to the body a progressive resistance against cold and heat, opposes infection of sores and wounds and shares in their cicatrization. Pigmented teguments are refractory to numerous cutaneous affections, such as furuncles, acne, etc., which often are merely doors through which more serious diseases may force an entrance.

The sun bath, enlarging the capillaries, determines an afflux of blood towards the skin; this ameliorated and regulated circulation of the blood helps to make the musculature remarkably firmer, better than the best massage would make it; thus the body finds again its natural harmony. The tonic power of the sun manifests itself also on the thoracic and abdominal organs; under its influence haemoglobin increases, internal secretions accentuate, digestive functions become regular, weight increases, strength is renewed. The sun not only acts on the physical side, it has a most efficient effect on the mind and the character of the patients. This is of great importance when one remembers how much this influence reacts on the physical, especially with patients who have to remain a long time confined to bed.

Pesology.

How must sun treatment be dosed? This is the aim of pesology, which is one of the most important chapters in sun treatment; time does not permit of my dwelling on it as it deserves and as I should like to do. On knowledge or lack of knowledge of pesology depends the result that we may expect from sun cure, and let us bear in mind that no physiotherapeutic method demands such strict individualization as heliotherapy.

A very current mistake consists in thinking that the sun bath is all the more efficacious if prolonged or taken when the sun is at its hottest; this is an inconsistency against which Nature herself seems to warn us.

We have laid down very precise rules for the practice of sun cure in order to prevent miscalculations and accidents. The principal rule is this: one must begin by only exposing the lower less sensitive parts of the body to the sun's rays. This will serve to show in what measure the patient bears the sun bath, and his further progress in insolation will be based on such observations. This method of derivation avoids congestion of the head and of the thoracic viscera. One must not take air and sun baths during meridian hours, especially in places at sea-level, where the ambient atmosphere enfeebles, produces congestion, annihilating the good effects of the solar rays. During the warm months of the year it should therefore be taken in the early hours of the morning.

Air and sun baths should always be taken gradually, the duration of insolation increasing by a few minutes each day, first exposing the feet, then the legs, then the thighs, the abdomen, the thorax, keeping the head covered with a simple linen hat. After a certain period of cautious advance, varying according to the case, the season of the year, the heat of the sun, the body becomes pigmented and can then bear several hours of sun each day. As a general rule, the sun bath, to be beneficial, should create a sensation of profound well-being, and each patient, whilst taking it and afterwards, should find himself invigorated.

Technique.

Before speaking of our technique, I think I ought to give you some idea of the installations in which we practise heliotherapy. I have neither the time necessary, nor the desire, to describe our thirty-four institutions in detail, but I would like you to see the first house we opened. It was then the only little boarding-house in our village; it is now one of our free clinics, opened in 1903. We fitted it up for the sun cure, by the addition of large balconies and of a roof solarium which probably was the first one to be built in Europe since the time of the Romans. Our contention is proved that heliotherapy can be successfully applied otherwise than in ruinously expensive palaces, for it is in this simple chalet that we obtained most of the cures to be subsequently shown and described.

It is indispensable to say a few words as to what has been the teaching of experience in regard to the application of the

sun cure. We will take the different localizations in their turn, beginning with Pott's disease and the most important articulations.

The Bed.

As the bed plays a very essential part in the treatment of such localizations, and is, so to speak, one of our principal tools, I take the liberty of insisting on some of its particularities. Its indispensable features are the following: It must be high, so that the balcony rails beside it may not obstruct the sun or the view, and to facilitate the nurse's work. It is fitted with large, smooth, easily running wheels, and can be rolled on to the balcony, to concerts, and even to the garden.

Special very hard mattresses are used. These never lose their shape, give the patient's body a maximum of support, do not induce perspiration, and prevent bed-sores. The spring mattress is composed of widely spaced strips of metal, thus ensuring perfect aeration of the mattress. Very emaciated patients are padded in with cushions.

Pott's Disease.

From the beginning we have discarded plaster appliances in cases of Pott's disease, finding that they bring about atrophy not only of the skin and muscles but of the skeleton itself. These cumbersome plaster devices have been replaced by simple arrangements of webbing straps which give sufficient immobilization while permitting the free access of air and sun to the injured places. Patients, especially children, are immobilized by a simple apparatus consisting of linen stays or braces, attached by means of linen straps to the head and foot of the bed itself. These can be opened and closed at will and cannot in any way interfere with the sun and air cure. Straps are also fastened down over the knees to keep them in position.

As soon as an x-ray examination shows the beginning of calcification of the vertebral block, the patient is placed in the ventral position, the thorax supported on a triangular cushion on which the patients can lean their elbows. To this physiological position *par excellence* we attribute a very great importance. This same treatment, as regards position, was advocated about a hundred years ago by two English doctors, Banting and Bamfield, and had been long abandoned when we again gave it the consideration it deserves. This position augments the lordosis and thus tends to correct the pathological curvature. It permits the insolation of the whole dorsal region and so very considerably develops and strengthens the muscles and ligaments.

Once cured, our cases of Pott's disease are all provided with what we call the "muscular corset," which is the best support of the spine for the future. In certain cases, in order to help to the correction of kyphosis by straightening of the shoulders, we use braces which are fastened to the foot of the bed.

[Dr. Rollier then showed a number of photographs of patients.]

1. A patient suffering from Pott's disease, with bad general condition, a very extended and prominent kyphosis, cured and straightened in quite a satisfactory manner by the proceeding just treatment.

from extremely painful Pott's disease red after eighteen months' treatment. The remarkable carriage of the child, his well-developed muscles, and the happy expression of his face were evident.

3. Another case of Pott's disease with very prominent kyphosis and marked atrophy of the thorax, both caused by plaster apparatus applied during many years. The patient was absolutely transformed after two years' sun cure, having recovered his muscles, and looking like an athlete.

4A. A case of Pott's disease complicated by mixed infection, with a sinus in the region of upper third of thigh, also with prominent curvature. The patient's muscles had been atrophied by wearing plaster apparatus for many years. He was also cured and partially straightened after twenty months' sun treatment.

4B. A picture showing the same patient in the dorsal position, lying on cushions, one of them replaced by a wooden block. The patient was first accustomed progressively to the wood by cushions filled with millet, then with sand. The advantage of the wooden block is that it offers a very uniform resistance and cannot hurt the skin, as such a block is always very smooth and dry, thus never producing scabs. It is generally very well tolerated by the patients, many of them preferring it to any other cushion.

4C. The same patient in ventral position, busy typewriting. To all of the patients is advised the work cure, which is applied systematically in most of our clinics.

5. A patient who knows how to pay part of his board and gives him a happy feeling of independence.

5. A balcony where this work cure is applied. On the foreground was a case of Pott's disease practising insolation on his back while doing basketwork.

This prompts me to say a few words on the work cure, which was first introduced into England by Dr. Paterson at Frimley Sanatorium, in the case of patients suffering from pulmonary tuberculosis, and which we organized first in our institutions for surgical tuberculosis. I wish to insist on this most valuable factor in the victorious conflict against mental depression, and which we consider to be a most precious adjuvant to heliotherapy. We always advise its practice for all our patients.

I personally consider the part played by work cure so important at the same time from a therapeutical, physical, and mental standpoint that I wish to show how we practise it in several of our institutions, by a film. It will give you an idea of how we had realized the work cure in one of our military clinics during the war.

[Dr. Rollier then showed a cinematographic film illustrating the work cure.]

Hip Disease.

For hip disease we use practically the same appliances as for Pott's disease. Plaster apparatus has been discarded here also, and has been replaced by continual extension by means of a sort of double bracelet made of linen or leather, fastening round the knee and ankle, which can be taken off at will. It always allows the insolation of the hip, and even of the whole leg. We also use a small sandal in order to avoid the tendency to equinism.

[Dr. Rollier again showed photographs illustrating cases.]

7A. A case which had been cured by this method, a very advanced case of hip disease, bad position, considerable shortening, partial luxation, external rotation, who arrived in this condition in a plaster apparatus.

7B. The same patient after eighteen months, quite cured by continual extension and sun cure. There was very satisfactory correction of the shortening, the muscles were developed, there was restoration of the whole organism, and with quite a satisfactory partial return of the articular function.

8A. A very severe case of hip disease, who arrived in a miserable condition, complicated with numerous sinuses of mixed infection. With all cases of this kind a good drainage of the sinuses is first assured, so as to avoid retention of pus, intoxication, and fever. Only when the drainages have been obtained is insolation practised in the region of the sinuses.

8B. The same patient after two years, cured, all the sinuses dried, restoration of the whole general health, and partial but quite satisfactory return of function.

I wish to add that with cases of hip disease with bad attitude the so-called bracelets which I have mentioned are not always sufficient for extension, and that a more complete appliance is needed. We then apply extension by means of bands of sparadrap. To make the extension more easy the leg is placed on a splint provided with wheels and placed on a small cart, the rolling of which is extremely soft, and which allows an energetic extension to be got with little weight.

9. A very serious case of hip disease with partial luxation of the head of the femur, very important shortening, bad position in flexion, severe secondary infection. The system of extension was demonstrated: the cushion which elevated the pelvis was to be noted, thus literally presenting that part to the sun's rays. It helped to avoid the bad attitudes and to correct them.

Tuberculosis of Knee.

In cases of tuberculosis of the knee we also have left plaster appliances. When the knee is painful it is placed in a widely opened splint, with continual extension. The injured limb is always placed on an inclined plane, which makes regression of capsular and periarticular infiltrations much more easy. The plane is more or less inclined according to the gravity of the case.

10A. A case treated after this method. He arrived in Leysin after resection of a tuberculous knee in a desperate condition. He had numerous wounds, not only in the region of the knee, but on the whole thigh. These wounds were consecutive to abscesses which had been incised and infected. There was bad position of the leg, ankylosed in internal rotation, very bad general health. The patient was feverish, cachectic, and suffered acute pain.

10B. The same patient after two years. The knee was cured, in ankylosis, of course, owing to the resection. There was cicatrization of all the wounds and the general condition was splendid. The young man was in perfect health.

11A. A patient with tuberculosis of the knee; focus in the external condyle, beginning of periarticular infiltration, muscular atrophy, bad general state.

11B. The same patient after one year and a half; the knee was perfectly cured, outlines quite normal, and complete articular function, while the general health was absolutely restored.

small lupus on right cheek. General condition poor. Habitus phthisicus.

24b. The same patient one year later.

24c. The same patient, thirteen years after establishment of cure, in excellent health and very active as a nurse.

25A. A case of Pott's disease with large curvature; general muscular atrophy, advanced tuberculosis of right lung, with repeated haemoptyses. Very bad general condition. Habitus phthisicus.

25B. The same man after one and a half years.

25c. The same man at the head of an important grocery store twelve years later.

Pulmonary Tuberculosis.

It has often been said, and is still believed by many, that heliotherapy is dangerous and of no help in pulmonary tuberculosis. We are of a different opinion, and our experiences tend to prove our position. It is true that most of the cases which we have treated accompanied surgical lesions. By careful examination of the lungs of our surgical cases we discover that about 30 per cent. of them have pulmonary foci as well. We have, however, also had in our care a whole pavilion of Swiss soldiers with pulmonary tuberculosis only and have never met with an accident of congestion, and no soldier who has been treated by sun baths has ever presented manifestations of haemoptyses any more, even if subject to them previously.

So we are convinced that the sun is not an agent of congestion, but rather a derivative, and might be compared to a cupping glass, the action of which we can regularize. It must, however, be well understood that the sun treatment, in such cases, must be applied exactly according to our derivative method—that is to say, by always beginning by the exposure of the extremities, and proceeding by prudent and slow progression. The sun should be dispensed, so to speak, drop by drop, when nearing the region of the thorax. It is also essential, as we have always said, that the heat of the midday hours should be avoided for the treatment, and one should have recourse to the earliest morning sun, while the air is not yet overheated.

Needless to say, no patient with a high temperature or in a state of intoxication should be exposed to the sun.

26A. Tuberculosis of right knee, very painful arthritis with synovitis. Very great swelling, fixation in bad attitude, subluxation of tibia.

26B. The same, showing the return of articular function.

27. Same patient.

oper
of fo
uria, high temperature.

27B. The same patient after one and a half years, absolutely cured, with complete restoration of the organism.

27c. The same two years later, one of our best nurses.

28. Very extended and painful tuberculosis of the left foot, mixed infection, large fetid wound, abundant suppuration, bad general condition. Spontaneous elimination of necrosed scaphoid took place. This spontaneous elimination of sequestra is extremely frequent, and we only practise surgical intervention when the sequestrum is enclosed in a cavity from which it cannot make its way out. In all other cases we leave it to the care and foresight of conservative Nature, who knows much better than the surgeon what must be expelled and what kept. This patient was cured after ten months' heliotherapy. The wound completely cicatrized after the elimination of the sequestrum. Twelve years later the patient had remained perfectly healthy, and could engage in all kinds of sport.

29A. A case of Pott's disease; very pronounced kyphosis, paraplegia, atrophy of muscles.

29B. The same patient after ten years; cure of paraplegia, complete refection of muscles. After her cure this girl we sent through the whole miserable experience of the Revolution. She had to escape to Siberia with her parents, living three months in an abandoned railway carriage. At last she reached Shanghai, where she became overtired by working to earn her own and her family's living, and in the meantime studying hard, her heart's desire being to qualify as a doctor. Having saved a little money she left Shanghai alone and went to London, where she began her studies. But all her difficulties had told too much on her strength, and soon it was discovered that she was suffering from renal tuberculosis. She was operated on in London, then came back to Leysin, where her nephrectomy wound is actually on a good way towards cicatrization. It was very interesting to see that after twelve years, and in spite of all her hardships, her back had kept admirably well all this time.

30A. A child, who arrived with tuberculosis foci—osteitis, periosteitis, advanced tuberculosis of both feet, right hand, and left lung. General condition very poor, advanced cachexia, high temperature, and albuminuria.

30B. The same one year later; all tuberculous foci cured.

30c. The same three years later, on his skis.

30d. The same ten years later; cure completely maintained, in spite of the patient having lived throughout the war in a German orphanage, where he underwent considerable privation.

X-ray Evidence.

If these photographic documents bear testimony to the success of heliotherapy, the demonstrations given by the x rays which are taken regularly of each patient, and the number of which now attains the total of 13,000, are much more convincing, and show with admirable clearness the process of cure of the most deep-seated lesions in the skeleton, a process which in many cases goes as far as to reconstruct it *ad integrum*. I should be very happy to show some of these skiagrams, but unfortunately time does not permit.

May I remind those interested in this question that this most important matter of the radiographic control of the results obtained by heliotherapy will be the subject under discussion in one of the most important chapters of our post-graduate course on heliotherapy at Leysin?

Preventive Heliotherapy.

If sun treatment can cure so many manifestations of tuberculosis, and maintain this cure, it can all the more prevent its outbreak. Experience confirms this. The sun bath, associated with open-air life and rational exercises, is the most active and surest prophylactic means, and for this reason acquires a social value surpassing its therapeutic value.

According to present views it is granted that tuberculous infection occurs, as a general rule, during childhood; reaching the age of puberty nearly all children (95 per cent.) have paid a debt to tuberculosis. Adenopathic and mesenteric ganglia are as outposts, where Koch's bacilli are kept in check. Since the germ of that disease is caught during childhood it is during that same time it must be fought and overcome; Koch's bacilli are incapable of harming so long as the bodily organism is fit to withstand. There is no surer way to attain this state of resistance than by air and sun. That is why, from the first, we have pleaded for its application in nurseries, orphanages, holiday schools, for in the schools, where constant discipline is the rule—discipline so often absent from family education—these principles of hygiene can be applied to children with most profit.

We have put into application this prophylactic means with delicate children and those predisposed to tuberculosis in our "school in the sun" established at Cergnat in 1910. Instead of educating children in rooms more or less without air and light, lessons are given them in open air and sun: this continual open-air life soon completely transforms the children; weak, ailing little beings, a prey to illness, become vigorous, brouzed children, with good musculature; fit to withstand fatigue and inclemency of weather, strongly protected against tuberculous invasion.

[A short cinematographic film was shown illustrating the "school in the sun."]

We know that hygiene is well applied in the schools of this country and the important part it plays in your open-air schools particularly. Our only suggestion would be that a larger place should be given to the sun, so as to place the children's bodies as much as possible in contact with the solar rays, at least during the gymnastic exercises.

This method could, without expense, be widely applied in all the schools. The beautiful parks and public squares, the glory of this country, would also be a splendid field, even if they were only used one or two hours a day for physical exercise in the sun.

Conclusion.

"Where the sun enters the doctor does not go" is an old popular saying, yet it contains quite a programme. Sun is indeed the incomparable remedy that foreseeing Nature has placed within the reach of everyone. It behoves us to make the most of it. The human body, being everlastingly threatened at all ages by many causes of impoverishment, must constantly be armed against them. Let it demand of the air and sun, these fundamental elements of hygiene, the resisting forces it is in need of.

These elements should have a larger place given them, in daily life and in the city. Not only modern towns should be built on such hygienic principles, but also the home. Housing has played an immense part in the genesis of child and adult tuberculosis: the community bears the responsibility of the waste of human lives through insanitary houses. Those principles should be propagated in all classes of society, that all may fully be persuaded that they are indispensable conditions of health and life.

SOME ASPECTS OF THE TREATMENT OF SURGICAL TUBERCULOSIS.

BY

JAMES TAYLOR, O.B.E., F.R.C.S.E.,

Visiting Surgeon to Robroyston Hospital for Tuberculosis, Glasgow.

DURING the last few years Glasgow, like the other large cities, has been giving more and more attention to the treatment of surgical tubercle. But it has only been since the war ended, when the hospitals which had been given over to the wounded were evacuated and returned to the use for which they were originally intended, that it has been possible to carry out the treatment on anything approaching the necessary scale. For over a year now we have had about 300 beds available for the treatment of surgical cases, and it will be my endeavour to give some indication of our difficulties and our experience of the various methods of treatment which have been recommended in recent years.

Perhaps the most striking results that have been published on the treatment of surgical tubercle are those of Dr. Rollier of Leysin, but his results are obtained where very special climatic conditions exist, and the same may be said, although perhaps to a less extent, of the results obtained by many others. In the course of the next few years this city will have a hospital as favourably situated as is possible within the borders of Scotland, but in the meantime we have to rest content with a hospital which is just beyond the city boundary, where our sunshine reaches us through an atmosphere not by any means free from smoke and dust. It will perhaps be of value therefore if I give some account of our experience of treatment under these less favourable circumstances, for it is likely that some considerable time will elapse before every tuberculous patient in this country can be treated under the most favourable conditions.

I should like to say something of the type of case which we have been admitting to hospital. As I have already explained, it is only recently that suitable accommodation has been provided, and so a large proportion of our cases come to us in a very advanced stage of the disease. They have been resting at home, attending the out-patient department of one of the large infirmaries, and being admitted from time to time to these institutions for scraping of sinuses, excision of joints, or other operative interference. A great many of our cases, therefore, have on admission sinuses which have been discharging for some time, and which have got badly infected. A number of others have abscesses on the point of bursting, and their health is often so undermined that it is almost impossible for us to save them from breaking down.

It was only a year ago that our hospital was opened and that we began systematically to treat cases of surgical tubercle. For a year before this we had a certain number of cases accommodated in a temporary hospital, without facilities for getting the patient into the open air. During this period I tried a group of about forty cases on trypsin without finding any evidence of improvement in any of the cases—that is to say, there was no more improvement in the cases having the injection than in the other cases enjoying the same hygienic conditions; as the treatment was by no means painless I gave it up entirely.

For a year now practically all our patients have been submitted to sun treatment, based on that described by Dr. Rollier in *La Cure du Soleil*. Our patients are gradually accustomed to the sunbath, the exposure being given according to a table, which is exactly the same as that of Rollier, except that fifteen minutes is substituted for his period of five minutes. That is to say, the first exposure is one of fifteen minutes to the feet only, and then on the second day the legs are exposed for fifteen minutes while the feet are exposed for half an hour. On the third day the thighs are exposed for fifteen minutes, the legs for half an hour, and the feet for three-quarters of an hour, and so on until the whole body is exposed. Then we gradually increase the length of the exposure of the whole body until the patients are having a sunbath of six hours a day. There are, of course, many interruptions of the treatment, for we have long spells when we have no sun at all, and in the spring and autumn it is only possible to give short exposures on account of the low temperature. In all cases with sinuses the wound is exposed under a thin piece of gauze.

As regards the results of this insolation, as we have observed it, there is no doubt that the improvement in most of the cases is marked, but we do not obtain the phenomenal results that Rollier gets. The general health of the child improves,

but it takes a long time before one sees much change in the local lesion. We do not see the extrusion of sequestra and the shelling out of diseased glands which he has described. It is easy to understand why this should be, for most of the ultra-violet rays are absorbed or reflected in their passage through our humid smoke and dust laden atmosphere. We have not the increase in the red corpuscles which is observed in people living in high altitudes, and we miss the intensifying effect of the reflecting snow and ice. I find myself in agreement with Lucas, who has been working in California, and Strauss, working in the lowlands of Europe, and believe that in such a climate as ours insolation is of great value as supplementing surgical measures, but that the solar treatment alone is too slow and doubtful to be depended upon. Even Hyde and Lo Grasso, who have reported very favourably of the sun treatment in the lowlands of America, only claim to get movement in joints in which the disease is in an early stage, while Rollier has obtained movement in joints in which there was already fibrous ankylosis.

As regards pigmentation of the skin, most of the patients seem to pigment well, but a number do not. I am not convinced, however, that they make slower recoveries than those who do pigment. It may be that once they have recovered there is less likelihood of a recurrence of the disease in the patient who browns well. This is a point on which I am not yet in a position to speak.

I should like now to refer briefly to our experience of the treatment of patients with cold abscesses. I have already mentioned the fact that many of our patients come to us with abscesses in an advanced stage of development, so that in a number of cases we have found it difficult to prevent sinus formation, and this is especially so during the winter months, when we have a minimum of sun and the weather is cold and damp. For some time we tried the effect of simple aspiration repeated with varying frequency, according to the rate at which the cavity refilled. In some cases this was enough, but in many others aspiration had to be carried on for a very long time before the cavity was obliterated, and in a number the abscess finally broke down. In one case of a large psoas abscess I aspirated the patient thirty-five times, and then the tuberculous infection travelled along one of the needle tracks, and the abscess discharged. In spite of every care infection ultimately took place and I lost the patient.

In a few of the cases of psoas abscess which were not responding to simple aspiration, I tried open operation with a very careful surgical technique—in fact the same technique as is recommended by Lane for the plating of fractures. The abscess cavity was exposed by a long incision, its whole lining carefully cleared away, the walls swabbed with ether, and the wound completely sutured up again. The results were only good in about a third of the cases. The wound began by healing well, but tuberculous infection of the scar took place, and when this broke down it usually resulted in a sinus leading down to the bony focus.

The use of modifying fluids has given us the best results in the treatment of abscesses, and of these fluids the one we have found most useful is the solution of iodoform in ether and oil with creosote and guaiacol, as recommended by Calot. Occasionally, when the fluid is very thick, we use his preparation of naphthal-camphor, but otherwise his No. 1 fluid is the one we almost invariably use. We have noticed that the one we almost invariably use. We have noticed that abscesses which were being treated by simple aspiration over a long time without definite improvement cleared up after a few injections of the iodoform-creosote mixture. One case, with a very large double psoas abscess extending into both thighs, who had been aspirated nineteen times, and had frequently as much as 750 c.cm. of fluid drawn off, completely healed after six injections, and this has been our experience with many other cases, although the results were less striking than in this one.

Considering only cases which are in hospital at present, we have 28 which have completed a course of aspiration and injection, and in 20 of these the abscess is completely obliterated, while in 7 others considerable improvement has taken place, fluid in one being reduced from 200 c.cm. to 10 c.cm., and in another from 1,200 c.cm. to 8 c.cm. The cure of these 7 will almost certainly be completed by another course. In one case there has been no response to the treatment. Another 8 cases are undergoing their first course, and are apparently doing well.

The treatment of sinuses is one of the most difficult problems we have to deal with; in the course of a few years I hope we shall seldom see a sinus. At present a large proportion of our cases have sinuses on admission. For the

grossly infected cases one can do little but try to provide free drainage, and depend on sun and air to increase the patient's resistance, but in the afebrile cases we have obtained good results from the use of Calot's paste. Of 41 cases which are in hospital at present under treatment by this method 21 have healed after one course, 16 are improved, and in 4 the course is still incomplete. Some of the results are quite striking. Two cases of hip disease with sinuses of two years' duration healed after a single course, while another patient with a cavity in the head of the tibia, which had been treated with trypsin and had twice been opened up, scraped, and disinfected with apparently no improvement, healed after six injections of paste. Almost all these sinuses are infected with pyogenic organisms, and those in which the staphylococcus is present seem to be the most resistant to treatment.

There is one other method of treatment which we are trying, but about which it is too soon to make any report. During the last two months Dr. Henderson (radiologist to the hospital) has started a series of cases on deep therapy. In tuberculous glands he has already obtained very good results, masses shrivelling to half their dimensions after a single exposure, but we are not yet certain what effect the treatment is going to have on tubercle of bone.

Among the cases that were sent to us for treatment were a number who were clearly syphilitic, while there were many cases in which the diagnosis seemed somewhat doubtful. This led us to carry out Wassermann tests in a series of nearly 300 cases of surgical tuberculosis, and we got a positive result in approximately 5 per cent. We found that we had to be extremely careful in the autisyphilitic treatment of patients who had a positive reaction and yet had a definitely tuberculous lesion. The injection of arsenical preparations had to be given in very small and carefully graduated doses; in fact in some cases it was impossible to give any injection at all, as the tuberculous lesion was liable to be rendered more active, old sinuses to break down, and new abscess formation to take place.

I have not referred at all to the orthopaedic treatment, which must be carried on at the same time as the general. Indeed, a very important part of the treatment of abscesses and sinuses is the immobilization that is obtained by suitable extension or plaster apparatus. I have been much impressed with the fact that even such improved hygienic conditions as we are able to offer, and the limited sunshine we have at our disposal, so increases the patient's resistance that, without lighting up fresh tuberculous mischief, we are able to correct by careful manipulation deformities which we had failed to correct by extension.

In conclusion, I should say that, while the treatment of surgical tubercle must anywhere be essentially conservative, in hospitals in which one has not the most favourable climatic conditions, operative interference combined with general treatment will give the most speedy, although perhaps slightly less perfect, results.

I have to express my indebtedness to Dr. Watson, superintendent of Robroyston Hospital, for his helpful advice, and for facilitating my work in every way, and to the house-surgeons for the excellent way in which they have carried out the treatment and kept the records.

SECTION OF PHYSIOLOGY.

Professor J. A. MacWILLIAM, M.D., C.M., F.R.S., President.

DISCUSSION ON BASAL METABOLISM.

OPENING PAPER

BY

E. P. CATHCART, M.D. GLASG., F.R.S.,

Gardiner Professor of Chemical Physiology, University of Glasgow.

BEFORE that very interesting and pertinent question, What is the significance of variations in the basal metabolism? can be answered much work requires yet to be done. The observation, which has been well established from data collected from all parts of the world, that there is a striking uniformity in the energy requirements of classes of people—for instance, farmers doing the same amounts of muscle work—suggests the possibility that a similar uniformity will be found in the basal metabolism—that is, the metabolism during complete muscular rest in the post-absorptive condition. The work of Du Bois and many others all points in the direction of

uniformity. If this uniformity be well established then the answer to the question will certainly be simplified, but no light will have been thrown on the nature of basal metabolism. In my contribution to the question I shall try to deal with some of the physiological phenomena associated with the consumption of oxygen and leave to others the clinical aspects of the question.

I think it may now be stated without fear of contradiction that the trend of modern work is to break down the old-time barriers which were believed to exist between the metabolism of the different proximate principles. The "active" substance of the cells is the complex material protoplasm, a substance which incorporates within its structure protein, carbohydrate, and "lipoid" material. Further, the work of Dakin and others has shown that the intermediate products of the breakdown of carbohydrates can be utilized in the synthesis of protein. It is now also beyond question that proteins in their turn can give rise to carbohydrates, and probably also to fat, as carbohydrates can undoubtedly form fat. Again, evidence—at present more indirect it is true—is slowly accumulating which shows that fats in their turn can give rise to carbohydrate, and therefore may take part eventually in protein synthesis.

It would seem, then, that in the metabolism of the animal, with this apparently free interchangeability between the various proximate principles, we have a state of immense resiliency, and that very wide fluctuations in the nature of the diet may be possible without casting an undue strain on the organism. Such is the deduction, and all the prolonged experiments on starvation would go to prove that such is the case when the organism has its own choice of material to call upon. But if, instead of throwing the tissues, so to speak, on their own resources—drawing for their energy and their wear and tear quota on the stores of the body—drastic changes are made in the type of food material supplied, the resulting changes are quite different. The organism is flooded with potential food material of one type, and in the attempt to utilize or get rid of it profound changes in metabolism result.

When we confine our attention exclusively to the variations which occur in the composition of the urine we are definitely limiting our field of vision, we are confining our attention to a single facet—namely, protein. The urine is practically confined (disregarding for the time the inorganic constituents) to the disposal under normal conditions of the waste products of protein metabolism, and it is only when the tissues are flooded with abnormal products, as in acidosis, that other material is excreted. It is undoubtedly true that profound changes in the composition of the urine can take place. Whatever else happens the course of the metabolism of protein can apparently be drastically interfered with.

The other two channels of excretion through which we gain evidence of changes in metabolism are heat loss and the respiratory exchange—that is, intake of oxygen and output of carbon dioxide. In many respects the information which is to be obtained from the study of the respiratory exchange throws a much more brilliant light on the intracellular changes than does either the study of the heat output or the end-products of protein metabolism in the urine. In the latter we are dealing only with the waste products of intracellular activity, whereas in the former—the respiratory exchange—we have to consider not only the waste carbon dioxide but the intake of oxygen which is absolutely essential for the running of the organism. Unfortunately the difficulty we encounter here is the manner of the distribution of the absorbed oxygen between the combustion of the various proximate principles—in other words, the interpretation of the respiratory quotient. The relation between the intake of oxygen and the output of carbon dioxide is a mere ratio. Unfortunately there seems to be a tendency amongst some workers to lose sight of the fact that the respiratory quotient is a quotient and nothing more. The respiratory quotient (R.Q.) does not represent a single change; it is a quotient of probably many components, the result of innumerable activities, the summation of many and varied metabolisms, although of course it is equally true that at times and under special conditions it may be so drastically altered that it may be said to represent a metabolism predominantly carbohydrate or predominantly fat. But even in these cases, with the R.Q. at the so-called 100 per cent. carbohydrate or fat level, it is not to be inferred that all other metabolic activities are in abeyance; we may not assume that, although ostensibly there is 100 per cent. combustion of fat, no other combustion is taking place. It is a self-evident fact that all tissues are living, that the active metabolic

"furnaces" are the muscle cells, that so long as a tissue is living it requires an intake of oxygen; carbohydrate, far less fat, cannot be expected to burn, so to speak, on a cold hearth.

The problem, too, is not one of the possible combustion of the elaborate molecules of carbohydrate or of fat but of intermediate products of these, probably of relatively simple and, in the end, very similar products. The intake of oxygen for the so-called combustion of fat is not only required for the actual combustion process but for participation in a series of preparatory oxidative changes, in which the oxygen-poor fat is converted into a series of oxygen-rich molecules, which can, when the demand arises, be readily utilized by the active metabolic cells.

The laws of Berthelot and of Hess, although they undoubtedly express general truths which may or may not be universally applicable, just like the ordinary everyday use of symbols in the expression of chemical equations, tend, when used without due thought, to confuse the issue. Thus the chemical equations commonly employed to express the complete combustion of carbohydrates and fat—

—probably do express, more or less correctly, the amounts of oxygen required for the complete combustion of these substances and the amounts of carbon dioxide which result from this combustion; but we neither obtain any clue to the actual chain of events which take place nor to the possible variables in these changes. It is well recognized that we can get respiratory quotients much below 0.7 and above unity. Thus in the possible conversion of carbohydrate to fat there may be an output of "atypical" carbon dioxide expressed by a chemical equation, on paper at least, as follows:

which has nothing to do with any combustion, but with a more intramolecular arrangement. Or, on the other hand, we may consider the excessive intake of oxygen requisite for the conversion of fat to carbohydrate, presuming that the deductions of Pembrey, Krogh, and others are sound, with a correspondingly low output of carbon dioxide—

When the possible fates of protein are considered the chemical formulae for their expression are well-nigh endless, and, as these various mutations are for the most part even more hypothetical and obscure than the foregoing, they may be neglected.

Too often the assumption, implicit perhaps, is made when metabolism is under consideration that we are dealing only with a series of katabolic phenomena, whereas metabolism is a blend of anabolic and katabolic processes, with the balance weighted, in the healthy, well-fed organism, slightly in favour of anabolism. The stimulation of the metabolism by various agencies is constantly referred to, but what does the statement really mean or imply? What is basal or standard metabolism, and what relation does it bear to the average daily metabolism?

The term "basal metabolism" has been objected to by Krogh, who has suggested the introduction of the term "standard metabolism" on the ground that "the basal metabolism of an organ is not a constant quantity but can be modified experimentally by varying the external conditions (for instance, the temperature) and may probably vary also from internal causes." Krogh by his term "standard" means to imply simply "that all variations in metabolism brought about by functional activity have to be referred to this quantity as a standard." He finds, speaking generally, that true basal metabolism is about 75 per cent. of the standard—that is, it represents the standard metabolism as ordinarily determined less the aggregative influence of functional activities like cardiac or renal activity, respiratory movements, etc., in the resting body.

True basal activity, then, would represent the sum total of the various changes which are taking place in the cells, simply for the purposes of maintenance, the ordinary wear and tear, and the repair of the same. When food is given or functional activity increases, does a mere stimulation of the basal metabolism, with a corresponding alteration of its character depending on the nature of the stimulus, take place, or is there a new type of metabolism superimposed on the basal? To take a rough simile—are we dealing with an

arrangement analogous to a gas fire supplied with a gas of constant composition and at a uniform pressure (which may from time to time but very gradually vary)? Let this lighted gas fire represent the basal metabolism: Is the metabolism of functional activity to be represented by, let us say, a spray of a combustible fluid sprayed directly on to the flame or by the combustible material being slowly introduced into the main gas supply? In the one case there would be a sudden burst of flame and heat without any material alteration of the original fire, a metabolism superimposed on the basal; or, in the second, we would have the actual character of the basal flame altered materially, according to the nature of the combustible substance introduced, and for a relatively long period; in other words, the basal and added metabolisms would be integral parts of the total metabolism. To my mind this is probably the most fundamental problem in the whole field of metabolism.

Benedict has made the general statement, with which I whole-heartedly agree, that basal metabolism is a function of the active protoplasmic mass of the organism. Few workers will, I think, be found to dissent from this sweeping statement. But what does it actually mean? What activities are comprised within this doctrine? It is undoubtedly true that the basal metabolism remains very constant over very long periods. Thus A. Loewy's figures, which extend over a period of fifteen years, are extraordinarily constant for oxygen intake in cubic centimetres—1888, 236; 1895, 228; 1901, 231; 1902, 238; 1903, 228. Both Magnus Levy and Johansson found a similar regularity over shorter periods, as did also Benedict and Cathcart. On the other hand, it has been shown just as definitely that by special treatment, such as a compulsory lowering of the food intake or of drastic alterations in the composition of the food, the basal metabolism may be markedly altered.

We may take it that the true basal metabolism is approximately a constant, and that in all probability it corresponds to the minimum chemical activity which is commensurate with the maintenance of life. The heat developed may be regarded as a necessary product, but, as Lambing puts it, not the physiological aim. For, be it noted, the external temperature at which the minimum is reached is not that of the organism itself, but is the temperature at which there is, to all intents and purposes, a balance between the heat loss and the minimal production of heat. When such a balance is obtained, as in the experiments carried out by Lefèvre, it was found that the standard metabolism was reduced by about one-third.

We have now to consider a question which is of immense importance to the clinician in the interpretation of the results obtained by the determination of the basal metabolism. Is there any variation of any kind in the so-called basal metabolism, and what is the effect of the different proximate principles on the metabolism?

Although the observations of Loewy already cited show that the basal metabolism remains approximately constant over many years, these observations were not intended to be more than approximations. It is obvious that in the consideration of variation one should inquire whether there is, in the first place, any diurnal variation in the metabolism in any way comparable to the diurnal variations which occur in temperature, pulse rate, and, as Lantieri and others have shown, in protein metabolism. Johansson, Landergren, Sonden, and Tigerstedt, many years ago showed well that, irrespective of whether the subject is fasting or fed, a definite reduction in the metabolic rate takes place during sleep. One of the most complete proofs of this observation are the long series of experiments which Benedict carried out daily on a fasting man over a period of thirty-one days. He found that the average increase of waking metabolism over sleep was just over 13 per cent. (varying from 27 to 4.5 per cent.). He further noted that the subject had a much greater intake of oxygen in the late afternoon than in the morning.

Figure 1 shows a most curious and interesting relation between the diurnal variation in the basal metabolism, the heat output as determined by rectal thermometer, and the protein metabolism as determined by the output of uric acid. It is an interesting speculation as to whether the variation in the basal metabolism is determined by the diurnal variation in the metabolism of the cell constituents, or whether the variation in the output of nitrogen is conditioned by variation of the causal factors underlying and determining the basal metabolism, or, finally, whether they are simply parallel

changes with little or no causal relationship. Although it might be argued that the fall in the oxygen consumption during sleep is due to the reduction in the gross muscular activity, the fall in the output of nitrogen is almost certainly not due to this reduction in activity, as it has repeatedly been shown that the output of total nitrogen is rarely increased, provided the supply of appropriate food is adequate, even after the most strenuous work. Leathes also showed that the output of total nitrogen was highest at night.

FIG. 1.—I and II, Carbon dioxide output (I with food, II without food) in grams per two hours (Johansson, Lindgren, Sonden, and Tigerstedt). III, Output of uric acid in milligrams per hour (Leathes). IV, Body temperature in degrees centigrade (Benedict and Snell).

Curiously enough, Benedict found a figure almost identical with the sleep-waking difference figure—namely, *circa* 13 per cent.—for the percentage variation of thirty-five “normal” men who had been repeatedly examined (in all over two thousand times) over periods varying from 4½ years to only 5 days—namely, 13.9 per cent. The average variation in the three longest periods was 4½ years, 14.9 per cent.; 2½ years, 25.9 per cent.; 2½ years, 12.1 per cent.; and in the three shortest periods—5 days, 15.3 per cent.; 6 days, 8.1 per cent.; and 12 days, 4.9 per cent. The subject whom Benedict and I studied practically daily for four consecutive months had a variation of over 20 per cent.

Further, the series of observations of Palmer, Means, and Gamble, which incidentally point to the influence of the time of the year or a seasonal variation, are of considerable interest. These workers found that with a subject whose body weight remained practically constant summer and winter (variation of 0.2 kg.), the heat output per kilo was 21.4 calories in the winter and 19.2 calories in the summer. The determinations were made under practically identical temperature conditions.

It is, of course, well known, and disputed so far as I am aware by no one, that the average woman has a lower metabolic rate than the average man, and that children have a higher metabolism than adults. Moreover, Benedict has shown that athletes have a higher metabolism than non-athletes of comparable age and weight.

The other question as to whether variations result in the basal metabolism from variations in the nature of the food consumed is also of primary importance. It is to-day a commonplace to say that the information to be gained from the examination of a chance sample of urine is negligible, and it is also true to say that the information to be gained, even from the examination of a sample taken from a twenty-four hours' specimen, is of little value unless the nature of

the diet taken by the subject is known. In my opinion this is equally applicable to the determination of the basal metabolism. It is perfectly true that basal metabolism is always determined in the post-absorptive state—that is, twelve to fifteen hours after food; but it is equally true that the condition of the body, the state of nutrition of the cells, is solely dependent on the food ingested, and it is very questionable if the cell contents will have reached a state of constant composition within the time given, irrespective of the previous nature of the diet.

It has been shown that the body has no great capacity for the storage of protein, and it has been stated by Rubner that protein deposited in the form of new tissue exerts no specific dynamic action. Still, the fact remains that protein ingested, as superimposition experiments have clearly shown, is not disposed of at once, that the output following the ingestion may be high for several days after, the duration of the excretion being dependent on the nature of the protein consumed. It is also true, as the following figures from Cathcart and Orr's paper clearly show, taking the Du Bois figure of 39.7 calories per square metro as an average figure, that the basal metabolism, strictly determined, is higher on the day following the ingestion of protein than on the days following the ingestion of either carbohydrate or fat.

	O ₂ Intake.	Cals. per sq. metro
Mean of all experiments on subject M. ...	242	39.8
Ordinary mixed diet ...	252	40.9
Carbohydrate diet ...	210	35.6
Fat diet ...	212	35.1
Protein diet ...	274	44.8

Again, it is, of course, a well-documented “fact” that protein acts on ingestion as a direct stimulant of metabolism, and that, as the brilliant work of Lusk has so clearly demonstrated, most if not all of this effect can be referred to certain amino-acids. As regards the effect of the previous ingestion of carbohydrate or fat, both of which can be stored in the organism, in my opinion the answer is equally plain.

Benedict and Cathcart record in their experiments with M. A. M., whose average oxygen intake was 240 c.c.m. a minute, that on the high, but not absolutely pure, carbohydrate diet the average intake was 234 c.c.m., and on the carbohydrate-poor diet it was 250 c.c.m. The experiments of Krogh and Lindhard are also of interest in this connexion; an analysis of all their data shows fairly conclusively that quite a marked difference exists between the oxygen intake on a carbohydrate-rich and a carbohydrate-poor diet. In three groups out of five the oxygen intake per minute on the carbohydrate-rich diet is very definitely below that on the carbohydrate-poor diet, and on the other two the intake on both diets was practically identical. The average of all the groups (including figures where the subject is stated to be on a fat diet, but where the R.Q. definitely shows that the glycogen reserve is being freely drawn upon, a reputed fat diet day with an R.Q. above unity) is 245 c.c.m. oxygen a minute on the carbohydrate-rich and 257 c.c.m. on the carbohydrate-poor days. Krogh and Lindhard, as the result of their work, conclude that the standard metabolism is not independent of the preceding diet. They found that when the diets are protein-poor the metabolism is lowest at intermediate quotients, and that it increases about 5 per cent. when the quotient falls to about 0.71 and about 3 per cent. when it rises to about unity. They also hold that their work shows that in this non-protein metabolism, both during rest and during work, the proportion of fat to carbohydrate katabolized is a function of the available supplies of these substances.

It is obvious, then, that the state of nutrition as regards the stores of food material in the tissues at the time of examination, even if the subject is in the post-absorptive state, plays a part in determining the level of the standard or basal metabolism, and that the nature of the previous diet is a factor which cannot be neglected in the final assessment. Is the converse true—namely, that when all the readily available stores are depleted and the organism is running at a low level the basal metabolism is depressed? This, again, is a problem of profound interest to the clinician, as so many of his patients are in a poor state, undernourished, or poorly developed physically. Benedict's figures, to quote a single series, show definitely that as the result of undernutrition the basal metabolism is undoubtedly below the so-called normal level—namely, the Du Bois standard. It follows that mere attention to the level of the metabolism, neglecting the physical state of the subject, may lead to very erroneous conclusions.

Still another factor which comes into operation and cannot be disregarded is the nature of the work done by the subject prior to the examination—not merely immediately prior, but on the previous day. Has he been active or at rest? What has been the duration of the rest period, and what has been the nature of the "rest" before the actual examination is made? What kind of night has the patient had? Have hypnotics been used? There is no doubt in my opinion about the prolonged after effect of work. It is true that, if the pulse be taken as the guide of quiescence, very often it rapidly, or fairly rapidly, returns to its normal figure; but this is no true index of the effect of muscle work on the various metabolic activities. Just as it has been shown in certain experiments on protein metabolism that a slight rise in the output of nitrogen may take place several days after the spell of work has been carried out, so there may be a resultant increased, though gradually diminishing, consumption of oxygen extending over many hours after the cessation of work, when all the more generally recognized post-work symptoms have completely disappeared.

The real difficulty which confronts the modern worker in his interpretation of the value to be attached to basal metabolism data is that we have no very clear indication as to the causal relationships between cell activity, oxygen consumption, and heat output. In conclusion, then, I wish to put before you certain considerations, largely it is true of a hypothetical nature but based on experimental data. In that muscle forms the most important and most uniform bulk of active metabolic tissue it will be perhaps useful to see if any possible explanation can be given, using this tissue as type material.

Grützner in 1887 had adumbrated the idea that there might be two different parts of muscle involved in contraction, an idea which was put forward much more definitely by Bottazzi in 1901 as the results of his experimental work with veratrine. He suggested that there were two active substances in muscle, (a) the doubly refracting material, and (b) the sarcoplasm; the first of these, being very irritable, is responsible for active movements, whereas the second, much less irritable, accounts for tonus. A few years later Mosso, on the ground of Perroncito's observation that apparently muscle was innervated by two types of nerve fibre, suggested that muscle might respond differently, depending on the source of the stimulus. This work on the possible double innervation of muscle has been investigated by many different workers, but so far without leading to any general agreement. One of these workers, de Boer, came to the conclusion that tonus is associated with the sarcoplasm, is carried on metabolically at the cost of a slow utilization of protein, and is under the control of the sympathetic system; whereas the rapid movement is the result of stimuli passing down the motor nerve, leading to rapid combustion of carbohydrate in the anisotropic substance.

Other work which throws some light on the complicated problem is that in which curare has been utilized. Many years ago Zuntz and Pfleger both stated that the administration of curare brought about a marked diminution in metabolism. This conclusion was controverted by Frank and Gebhard, and later by Frank and Voit, who found that provided the dose of curare was not too great there was but little diminution in metabolism—a statement confirmed by the excellent work of Tängel, Mansfield and Lukács, in the light of the possible double innervation and the fact that curare in moderate doses only affects the motor nerve endings, re-examined this question. They determined the gaseous metabolism of an animal given a dose of curare which just sufficed to abolish the capacity of muscle to respond to indirect stimulation before and after complete section of all nerve supply to the muscles of the hind limbs. They found that although this procedure brought about a denervation of only about one-third of the total musculature of the animal a marked reduction both in the intake of oxygen and the output of carbon dioxide took place; no such reduction occurred when the sympathetic supply alone was destroyed. In a later paper Mansfield found that with massive doses of curare the sympathetic nerves can be put out of action. Incidentally he suggested that the so-called mechanical tonus is identical with chemical tonus. Still later Ernst, working under the direction of Mansfield, published the results of an investigation into the nature of the source of energy for tonus and rapid contraction. He found that the glycogen content of muscle rapidly diminished as the result of stimulating the

sciatic nerve, but that if a dose of curare were given (just sufficient to throw the motor nerve out of action) stimulation no longer caused the disappearance of glycogen; indeed, in some cases, the stimulated side actually contained more glycogen than the "normal" side. The inference to be drawn is that the chemical expression of rapid contraction and of tonus is different.

It would seem that there is a good deal of evidence, both direct and indirect, in support of the view that the activity of muscle is not a single simple phenomenon, but that we have to deal with at least two types of activity, one of which seems to be associated with the sarcoplasm, and to which the term "tonus"—plastic either in the sense of Sherrington or of Langelaan—is applied, and the other, which is associated with the sarcolemma, the activity of which is evidenced by the ordinary rapid contractile response. I do not for a minute pretend to decide between the conflicting views, but there is at least presumptive evidence in favour of the view that the first is under the control of the sympathetic, whereas the other is under control of the ordinary efferent motor nerve from the anterior horn. Again, the suggestion has been put forward that the tonic type is mainly associated somehow with the metabolism of protein, whereas the other is mainly associated with the metabolism of carbohydrate. The work of Pechelaring is certainly in favour of the view that the output of creatinine is in some way related to "tonus," and again the experiments of Cathcart and Loaches on the effect of involuntary work, in the form of shivering, on the distribution of nitrogen in the urine, tend to show that the metabolism of uric acid is of a peculiar order. It is very interesting that both of these substances, creatinine and uric acid, were found by Polin, according to his well-known work on the composition of the urine, to belong to the limited class of substances to which he gave the name of tissue or endogenous or constant metabolic products. Quite rightly, I think, he held the view that the demand or need for protein by the organism is small, and he clearly demonstrated that the more the total nitrogenous metabolism is reduced the more prominent do these constant metabolic products become.

Is it too presumptuous to suggest that these various endogenous products, not merely creatinine, actually represent the effects of the metabolism of the sarcoplasm—in other words, they are the metabolic products associated with "tonus"? In support of this hypothesis may be submitted the very interesting observations of Leathes, which were later confirmed by Wolf and Osterborg, on the diurnal variation in the output of creatinine and uric acid already referred to. It was found that the uric acid and also creatinine output was lowest during the hours of sleep—that is, of the most complete muscle rest—at the period when, to use Sherrington's interpretation of tonus, the postural contraction would be least in evidence. It is, of course, a fact of common knowledge that "tonus" is at its lowest during deep sleep (Lombard's work on the knee-jerk, for instance), just as it is reduced in positions of complete rest during the waking period. I should like to go even farther and suggest that the true basal metabolism is a phenomenon separable from metabolism in general, and that it is based for the most part on the sarcoplasm or "tonus" metabolism. It is generally admitted to be the lowest limit of metabolism compatible with normal tissue activity, and that it is certainly a function of the mass of the active metabolic tissue, of which muscle is the predominant material.

It is found that, just as is the case with uric acid and creatinine, there is a marked diminution in the gaseous metabolism during the hours of reduced tonicity—that is, metabolism during sleep (see Fig. 1). This is well established by the during sleep (see Fig. 1). This is well established by the experiments of Johansson, Landergrén, Sonden, and Tigerstedt, and of Benedict. If it be demanded that the heat output shall fall into line with these observations, then the continuous records of Benedict and Snell show this to be the case (see Fig. 1). The general result, which could readily be added to, is well summed up in Fig. 1, which I have constructed from the above observations. It is realized full well that such a hypothesis is in no way an explanation of one of the most interesting problems of physiology, but it is put forward in the hope that it is a contribution towards a narrowing of the issue. If it serves to emphasize the danger of drawing too far-reaching conclusions from basal metabolism data, from all types of cases and all kinds of patients varying physically and psychologically, it will have served a useful purpose.

DISCUSSION.

Dr. J. B. ORR (Aberdeen) referred to some of the difficulties in the accurate determination of true basal metabolism, particularly to the influence of the psychic condition of the subject and the state of the endocrine glands. The theoretical lowest level of metabolism was unattainable under experimental conditions. In endeavouring to measure very low levels of metabolism we were really dealing with a pathological condition, because intake of nourishment and reactions to other stimuli, either chemical or nervous, were normal functions of the cell. He disliked the conception of normal metabolism as true basal metabolism with an addition superimposed. True basal metabolism was an abstraction. What we really studied was different levels of metabolism with varying degrees of intensity of many functional activities. In studying the influence of any factor on the rate of metabolism it was of course necessary to have a fixed base line, but that was merely an arbitrary condition where, as far as possible, the different factors that influenced metabolism were controlled, preferably at a low level, and specified.

Professor J. C. MEAKINS (Edinburgh) said that his own observations had been chiefly made in pathological conditions. The value of determinations of basal metabolism depended on the care with which they were made. If proper precautions were not exercised a valuable method for the study of disease might fall into disrepute. He described the conditions of observations in his wards and emphasized the importance of mental apprehension as a disturbing factor. It was sometimes necessary to accustom the patient to the procedure by dummy experiments.

[Professor Meakins showed slides demonstrating abnormal levels of basal metabolism in thyroid disease and the changes due to treatment and operative interference. The effect of injections of adrenaline on basal metabolism, respiratory quotient, and blood-sugar content was also pointed out.]

Dr. G. B. FLEMING (Glasgow) discussed the influence of growth on the basal metabolism. He explained that the energy expended in growth must be included in determinations of basal metabolism in children. This probably accounted, to a large extent, for the high basal metabolism found in growing children. He showed that as the rate of growth decreases the basal metabolic rate also decreases.

Dr. LEONARD HILL (London) said that basal metabolism as determined by the respiratory exchange was liable to be raised by the inevitable obstruction to breathing due to the apparatus used. It could also be affected in the same way by voluntary hyperpnoea. Figures for the basal metabolism of subjects under many normal conditions were given. He then went on to discuss the influence on basal metabolism of rate of heat loss, quoting experiments where this factor was measured by the kata-thermometer. In the tropics basal metabolism might be one-third lower than in temperate climates on account of this. The rise in basal metabolism due to more rapid heat loss constituted an important part of the benefit resulting from open-air treatment. The effect was believed to be attributable to the open air and not to sunlight.

Dr. C. M. WILSON (London) referred to the question of the depth of pulmonary ventilation as affecting basal metabolism and of standards for patients in a state of real emaciation. In several patients suffering from menorrhagia with a high initial basal metabolic rate the exposure of the thyroid to x-rays had produced a markedly beneficial effect.

Professor CATHCART, in reply to the points raised, said that the technique of determinations of basal metabolism required experience.* The rate of pulmonary ventilation might exercise an enormous effect. Sleep lowered the figures obtained as much as 15 per cent. At present we did not know what basal metabolism really was, but it was certainly the result of the interaction of a large number of factors. Personally he considered the question of muscle tonus as one of the most important of these.

* The portable basal metabolism apparatus used is the latest type of that of Collip and Collins. It can be obtained from Messrs. Boston, through Messrs. Thomson.

THE DIAZO-REACTION, WITH SPECIAL REFERENCE TO URINE IN MEASLES.

(PRELIMINARY NOTE.)

BY

GEORGE HUNTER, M.A., B.Sc.,

Institute of Physiology, University of Glasgow.

THE cause of the diazo-reaction in urine has been attributed to a variety of substances. Clemens (quoted by von Noorden) claims to have isolated the sodium salt of the substance responsible for the reaction. This substance contained 4.5 to 5.4 per cent. nitrogen. Others assume it to be due to chromoxy-proteic acids or to ill-defined members of this group of substances (Noubauer-Huppert²). Weiss³ is emphatic that urochromogen is the substance responsible for a positive diazo-test. Engeland⁴ isolated from 40 litres of normal human urine a small amount of histidine. He thus suggests that iminazole derivatives primarily cause the diazo-reaction in urines. Hermanns and Sachs⁵ consider that in urines from tuberculous patients an oxidation product of tyrosine is responsible for the diazo-reaction. In the urine of a patient with acute liver atrophy these observers found oxyindolacetic acid.

The methods of carrying out the diazo-reaction in urine have been very varied. Suffice it to note here that, to avoid deamination of colour giving amino-acids by the free nitrous acid of the diazo-reagent, the latter should be made alkaline before the addition of the urine to be tested. For reason stated by Koessler and Hanke⁶ sodium carbonate is for this purpose preferable to sodium hydroxide or to ammonium hydroxide.

So far as the author is aware, the diazo-reaction in urine has not previously been studied from a quantitative aspect. To find out the relative importance of the substances in measles urine giving a colour with the diazo-reagent a quantitative procedure has been attempted.

Five hundred c.c.m. of a mixed sample of measles urine were quantitatively fractionated by lead acetate, lead acetate and baryta, and by mercuric acetate. A portion of the last fraction was further precipitated with silver nitrate, followed by silver nitrate and baryta. The colour value developed by the Koessler and Hanke⁶ diazo-reagent was measured in the various fractions. The colour standard employed by these workers for histidine was here used as a standard. An orange light filter placed over the eyepiece of the Duboscq colorimeter was consistently used throughout the measurements in order to obtain a match with the yellow colour developed in certain fractions. The total colour value of the original 500 c.c.m. of urine was found to be 86,500 mm.

The lead acetate fraction had a total colour value of 770 mm., the lead acetate baryta fraction a total colour value of 4,400 mm., the mercuric acetate fraction a total colour value of 87,500 mm., and the final filtrate a total colour value of 10,000 mm. The sum-total colour values of the various fractions is greater than the original for the reason that there are certain substances in the original urine which inhibit colour production. The portion of the mercury fraction taken for the silver baryta separation has an original total colour value of 12,600 mm. In the silver baryta fraction there were recovered 12,500 mm., or almost 100 per cent. The silver fraction and the final filtrate gave no colour.

From 1 litre of urine the silver baryta fraction was obtained as above. Creatinine was separated by precipitation with picric acid, the filtrate retreated with silver baryta, and the latter fraction finally precipitated with mercuric chloride. From this well-washed precipitate there was obtained about 0.1 gram of pure histidine monohydrochloride. (The amount actually present per litre was estimated at 0.31 gram.) It had the following properties: melting-point, 253° to 254°; melting-point, with decomposition, of the picrolonate, 231 to 233°. The microscopic appearance of both these salts agreed with authentic descriptions and with the same salt of histidine obtained from a different origin. There was found 16.9 per cent. (calculated 17 per cent.) Cl. The molecular colour value was 114.5 million mm. (Hunter).⁷ It was positive to Knoop's test.

The substance mainly responsible for the colour now accounted for by histidine was not isolated, but partially purified and relatively concentrated solutions gave reaction indicating a phenolic constitution.

Conclusions.

1. In the urine from patients suffering from measles, histidino is responsible for about 85 per cent. of the colour developed by the diazo-reagent.
2. In measles the output of histidino in the urine is increased.

The writer is indebted to Dr. Elliot, of Ruchill Hospital, Glasgow, for the material, and to Professor E. P. Cathcart for much help throughout the work.

SECTION OF DERMATOLOGY.

H. LESLIE ROBERTS, M.D., C.M., President.

DISCUSSION ON

THE ETIOLOGY OF SEBORRHOEA AND SEBORRHOEIC DERMATITIS.

OPENING PAPERS.

I.—R. CRANSTON LOW, M.B., F.R.C.P.,

Lecturer on Diseases of the Skin, University of Edinburgh.

THE subject of seborrhoea was discussed in this Section of the British Medical Association in 1901 at Cheltenham when Colcott Fox introduced the discussion and Sabouraud and others took part in it. For some years prior to that much had been published, especially on the bacteriological side of the question, notably by Unna and Sabouraud. Some of that work has been confirmed since, and is generally accepted now, but many of the points raised then are still undecided, and unfortunately the whole subject is still in rather a confused condition.

So many different conditions are included under the terms "seborrhoea" and "seborrhoeic dermatitis" that it is necessary, in discussing their etiology, to divide them up into their clinical varieties. They fall into two groups—namely, (1) the true oily seborrhoea, using the word in its true meaning, and (2) the so-called seborrhoea capitis and seborrhoea corporis or seborrhoeic dermatitis. Both these groups have certain things in common, and it is impossible in discussing etiology generally to keep each clinical variety separate. As to the clinical lesions, I think most of us will be in agreement, but it is quite another matter when it comes to their interpretation.

Strictly speaking the term "seborrhoea" should only be applied to the oily condition of the skin due to increased secretion of sebum. Seborrhagia, steatorrhoea, flux sebacea (Kayer), and seborrhoea oleosa (Hobin) are the older names for the condition. It affects chiefly the scalp, face, central area of the body, back and front, and the flexures, and is generally accepted now as due to increased secretion of the sebaceous glands. A close inspection of the skin will reveal the large and patulous orifices of the sebaceous glands and the oily condition of the skin and scalp hairs. But as it is often associated with increased sweating as well, it is difficult to dissociate the two conditions. Unna prefers the term "hyperidrosis oleosa," as he believes that the greater part of the oil is derived from the sweat glands. No great support has been given to this theory as it does not agree with the clinical facts. Probably there is right on both sides, the increased sebaceous gland activity being accompanied by some hyperidrosis.

This oily condition of the skin is the basic factor in all forms of seborrhoeic eruption. Is it an increase of a physiological process or is it due to an inflammatory infection of the oil-producing glands? The work of Sabouraud, Unna, and others has established the fact that a bacillus is always present in the sebaceous material in such cases, but, although Sabouraud claimed that the organism caused the condition, the tendency to-day seems to be to disagree with that view. All the evidence points to the condition being an amicrobic functional disturbance in the first instance. Before birth the sebaceous glands are very active, as is shown by the vernix caseosa, and at birth the infant frequently shows fatty plugs

in the sebaceous gland orifices of the face, especially the nose. To this cause also the greasy adherent scales on the scalp of young infants—crusta lactea—are probably due. No one would suggest that these conditions at birth are of microbic origin. From birth on till puberty oily seborrhoea is not much in evidence, but with the development of the sexual glands the sebaceous glands become fully developed and the hair grows on the face, etc. It is difficult to estimate what is the normal oiliness of the skin, and there is no standard by which we can go. In some individuals the skin is probably naturally very much oilier than in others. It may be an hereditary characteristic. It is well known that the dark races have much oilier skins than the white. You may get ichthyoties with dry skin and deficient skin-gland secretions; why not other skins with increased glandular development? On the other hand, there may be other acquired factors which stimulate the skin glands.

Foods.—That diet is important no one will deny. Certain foods in excess, such as too much fat, starch, or sugar, have been blamed for making the skin oily. If a great deal of fat is deposited under the skin it is readily accessible to the skin glands. Montgomery states that all starches and sugars have, in process of digestion, to be turned into glucose, and if starch and sugar are taken in excess they are not all absorbed as glucose through the portal system and a great deal is thrown, through the lymphatic and thoracic ducts, into the circulation, without passing through the liver. This sugar, which is not so elaborately digested as that which passes through the liver, he considers, is irritating to the skin glands and causes their increased activity. He also states that many persons with seborrhoeic eczema have enlarged livers, probably from fatty infiltration or excess of stored glycogen. This might cause obstruction to the passage of glucose through the liver, and again the sugar is thrown direct into the circulation without going through the liver. Excess of sugar in the diet may also lead to increased fermentation in the bowel by its constipating effect, and the products of fermentation may lead to sebaceous gland irritation. Sterling pointed out that the milk fats, either as milk, cream, butter, or cheese, are more likely to lead to a deposit of fat in the skin than meat fats. The milk fats are oil emulsions, whereas in meat fats the fat cell has a membrane which has to be digested before the fat is absorbed, and therefore all milk fats are more quickly and easily absorbed than meat fats. Also the fatty secretion of the sebaceous glands in man and the higher animals consists almost entirely of cholesterol esters. These are very little liable to fermentation, and bacteria do not grow well in them. By taking a large quantity of milk fats the sebaceous gland secretes fats which are peculiarly liable to bacterial infection, hence excess of milk fats leads to infections of all kinds in the sebaceous glands. Alcohol, by dilating the skin vessels, may indirectly lead to stimulation of the sebaceous glands.

Apart from foods, there are some conditions which tend to increase the activity of the oil glands.

Heat.—Working in heated atmospheres and strenuous exercise increase the circulation in the skin, and in addition to causing sweating also increase the secretion of oil.

Clothing, etc.—The wearing of heavy clothing, especially flannel, is a well-known contributory cause of seborrhoeic eruptions. Want of cleanliness, irritation of dirt and dust, have also been blamed.

Anaemia.—It is well known that in anaemia the skin is often oily. The anaemia may lead to lowered oxidizing powers of the tissues due to want of sufficient oxygen and therefore to a tendency to the deposit of fat in the tissues.

Toxaemias.—The circulation of toxic substances in the skin may also excite the activity of the oil glands. This is especially the case in intestinal toxaemias and constipation. Acute infections such as the exanthemata and influenza are often followed by seborrhoeic eruptions, or existing lesions are aggravated.

Endocrine Glands.—The possibility of the endocrine glands having an influence on the skin oil secretion must not be lost sight of. Hyperthyroidism makes the skin softer and oilier than normal, but the excessive thyroid secretion may only be the result of some toxæmia which is really the primary cause of the condition.

Diathesis.—Lastly, it has been suggested that seborrhoeic conditions are due to an underlying disposition or diathesis of the patient. Darier describes the seborrhoeic diathesis as "la kérose." He considers it as an anomaly of the skin and not a disease in itself; not a trouble of nutrition of the skin, but a modification of the circulation of the glands and

the keratinization of the epidermis. Ho-holieros, that individuals with this constitution have a hypertrophy of the sebaceous glands which lasts during their active sexual life. This condition makes their skin liable to the various infections known as seborrhooids, and later ends with atrophic changes in the skin glands and hairs such as seborrheic alopecia.

Barbor and Semon in 1918 again draw attention to this theory and support Darier's view that the tendency to seborrhoea occurs in a special type of individual, who is particularly liable to infections and inflammations of a seborrheic nature. They think that it may exist in infancy or may appear *de novo* in adults. They suggest that such individuals are suffering from a relative acidosis, and that, owing to insufficient intake of the mono- and di-sodium phosphates and carbonates in the diet, the normal alkaline acid equilibrium is upset. They point out the resemblance of this condition to what Czerny describes as the oxalutic diathesis in children, where their skins and mucous membranes are specially liable to bacterial infection, so that they suffer from adenoids, enlarged tonsils, glands, and skin infections. Barbor and Semon suggest for this dyscrasia the term "status seborrheicus."

If this state is in some cases an acquired one due to faulty diet or digestion this theory is not so very far removed from the toxic and food theories. It has a great deal to recommend it, as it fits in with the clinical experience that all the conditions under discussion have something in common in the appearance of the skin and eruptions, and that appearance we are accustomed to describe as seborrheic.

Now that we have considered seborrheic conditions from the general standpoint, let us take each condition separately, and see wherein they differ in their special etiology.

The True Oily Seborrhoea.

This has already been considered, and the possibility of its being due either to an infection of the sebaceous gland with Sabouraud's bacillus, or to some general condition, either diietetic, toxic, or error of metabolism. But before leaving the subject mention must be made of associated conditions. The association of *acne vulgaris* with seborrhoea is well known, but as the cause of *acne* is hardly relevant to the subject under discussion I do not propose to deal with it further. The question as to whether oily seborrhoea leads to alopecia will be considered later under the next heading.

Seborrhoea Capitis.

Next let us consider seborrhoea capitis, and by that is meant the scaly condition of the scalp usually termed dandruff. Under this heading two conditions are usually included: (1) the dry scaly condition called by Sabouraud pityriasis simplex, and (2) the oily scaly condition which Sabouraud calls pityriasis steatodes. This latter condition may later become more inflamed, and lead to the so-called seborrheic eczema of the scalp. You are all acquainted with Sabouraud's views that pityriasis simplex is due to the spore of Malassez, and pityriasis steatodes to the spore of Malassez and the *Staphylococcus epidermidis albus*, and seborrheic dermatitis to these two organisms together with the seborrhoea bacillus; and with Unna's view that seborrheic dermatitis is due to the morococcus (*Staph. epidermidis albus*), so that it is not necessary to elaborate them further. I must say, however, that I have never been able to see any very clear line of distinction between the condition called seborrhoea sicca (pityriasis simplex of Sabouraud) and the more greasy form of the condition where the scales are oily and where there is occasional crust formation. It has always seemed to me that the one is probably only a further stage of the other. They have both this in common, that there is desquamation from the surface of the scalp, and the lesions are obviously inflammatory in nature, and all the evidence, both clinical and microscopic, points to an organismal infection of the skin and glands. Sabouraud ascribed pityriasis simplex to the spores of Malassez, and pityriasis steatodes to the spores and *Staph. albus*, but I do not see why one should go out of one's way to complicate matters when the same cause might operate in both cases. If one assumes that the infecting agent or agents in pityriasis simplex are simply growing in the superficial horny layers of the scalp it would lead to a branny desquamation such as one sees from the growth of the *Microsporon furfur* in pityriasis versicolor. If the condition goes deeper into the epithelium and pilo-

sebaceous follicles of the scalp, then pityriasis steatodes would be produced; and if the infection goes deeper still in the epithelium and corium, then you get more marked inflammation with the production of seborrheic dermatitis. In favour of this view is the well-known fact that pityriasis simplex is usually very amenable to treatment, as one would expect in such a superficial infection, whereas the other conditions are much more resistant, probably because, being deeper, it is more difficult to get the therapeutic agent into contact with the infecting agent. The one form often leads on to the other, and usually in the same sequence—first the simple scalliness, then oily scalliness with or without crusting. As Sabouraud's bacillus, the spores of Malassez, and the *Staph. epidermidis albus* are present in all three conditions, and as these organisms have all been found on apparently healthy skin, I do not see that one is able, in the present state of our knowledge, to decide what part each plays in producing the infection.

Before leaving this subject mention must be made of a condition which is generally allowed to be the result of seborrhoea capitis—namely, seborrheic alopecia or the common form of baldness. Sabouraud ascribed this to the oily form of seborrhoea, and held that it was due to the prolonged action of the seborrhoea bacillus and its toxins on the hair papillae, but I think it is a general experience that alopecia more often follows the scaly form of seborrhoea capitis, and that, if the hair remains oily, it may turn grey early but usually does not tend to disappear. Darier would include it under his condition of korosis, and puts it down to an atrophy through fatigue subsequent to the excessive stimulation of the hair and sebaceous glands in the earlier stages of the disease.

The wearing of hard hats, too much brain work, want of exercise, and various other conditions have been suggested as at least predisposing causes to the condition; but, so far as I can find out, no one has suggested what I think is the obvious predisposing cause—namely, wearing the hair short. Alopecia is rare in females and appallingly common in men. The only difference between the way in which men and women treat their hair is that the one wears it short and the other long. The hair was meant to be long, and I take it that the normal stimulus to the growth of the hair is the long hair hanging down the back and blowing in the wind. There is a gentle pull on the hair bulb by the weight of the hair which reflexly through the nervous system keeps the hair in tone and stimulates the circulation in the bulb. If one keeps the hair short, one removes the stimulus to the healthy growth of the hair, and the seborrhoea of the scalp attacks the hair bulb and soon destroys it. Women may have seborrhoea capitis for years, and it practically never leads to the degree of alopecia seen in men. It is a well-recognized fact that all organs which are not used as they were meant to be become weak and liable to the attack of infecting agents. Men also go much more frequently to the hairdresser than do women, and I think it is there that they are probably infected with seborrhoea. The revolving brushes which some hairdressers use are probably particularly to blame, as considerable force is applied and the organisms removed from a previous customer's scalp are vigorously rubbed into that of the next one. This repeated reinfection with a fresh virus from another individual would account for the recurrence of seborrhoea capitis in men in spite of treatment. Most men are probably infected in boyhood, and at first the inflammation of the scalp leads to hyperaemia and stimulation of the growth of the hair. This is the stage at which most youths are at 17 or 18 on leaving school, and the same youth at 24 years or so is beginning to get bald. The only men who have, as a rule, good heads of hair are some of the professional musicians, and that is not because they are musicians but because they wear their hair long.

Seborrhoea Corporis and Seborrheic Dermatitis.

This includes the lesions which start as papular, papulovesicular, and vesicular, and end as scaly and crusted areas of a yellowish-red colour, usually spreading peripherally, sometimes clearing up in the centre, and typically seen on the sternal and interscapular regions. There are also the similar inflamed lesions which may occur on the scalp and spread down behind the ears on to the neck, in the axilla, groins, etc. There is no difficulty in assuming the parasitic origin of the more superficial forms of seborrhoea corporis where there are circinate lesions spreading slowly outwards. Here again the same three organisms as occur in seborrhoea capitis may be found, and here again I do not see how one is to decide which organism or combination of organisms is the cause.

race have oily skins; moreover, dark-complexioned persons as a rule have larger and more actively secreting sebaceous glands than blondes.

On the other hand, there is a pathological seborrhoea, and it is when this exists that the various types of eruption to which the epithet "seborrhoeic" is attached are apt to make their appearance. I am convinced that in this condition we are not merely dealing with increased secretion of sebum and sweat, but also with an alteration of their composition, and that it is this as yet not accurately determined change of composition, rather than the increase in the amount secreted, that renders the skin liable to active invasion with micro-organisms which the normal skin is able to resist. In favour of this view is the fact that, although in cases of seborrhoeic dermatitis there is usually obvious hypersecretion of the sebaceous glands, this is not always so. Indeed, one may meet with typical seborrhoeic dermatitis in ichthyotic persons.

There is, in fact, a seborrhoeic state, as Semon and myself insisted from our study of cases met with among the troops, and I may here say that, although further research carried out with Dr. Ryffel and others has caused me to modify my views somewhat, they remain substantially the same as when Semon and I published our paper five years ago. I can, perhaps, best give a vivid picture of this seborrhoeic state by describing the clinical appearances of an acute case; such cases, so common during the war, are still sometimes met with in civilian practice.

The face, scalp, ears, and neck are flushed, giving the patient a congested or plethoric appearance; the sebaceous glands are visibly hyperactive, as also are the sweat glands, so that even in cold weather droplets of sweat may be seen on the forehead, nose, and upper lip. If one tests one of these droplets with litmus paper it will usually be found to be strongly acid, much more so than the visible sweat obtained in normal people, and the high acidity cannot, I think, be due altogether to admixture with sebum. The vermilion borders of the lips are covered with a kind of yellowish scum, and examination of the nose, throat, and nasopharynx will show congestion of the mucous membrane, catarrh, and reddening and hypertrophy of the lymphoid follicles on the posterior pharyngeal wall. The urine is almost invariably highly acid, even if dilute, but occasionally the apparent anomaly occurs that is met with in some cases of diabetes—namely, that the urine may be only slightly acid, neutral, or even faintly alkaline when first examined, but on administering alkalis one finds that for a while it becomes more acid.

In this state the resistance of the skin and mucous membranes to bacterial invasion is diminished; in other words, there is apt to result what may be termed a catarrhal inflammation both of the skin and of the mucous membranes of the nose, nasopharynx, eyelids, conjunctiva, penis, and vulva. The micro-organisms concerned are chiefly the pyogenic cocci, particularly the *Staphylococcus albus* and *aureus*; of less importance are the acne bacillus and the so-called "bottle bacillus," which affect the skin alone. These various organisms produce eruptions whose clinical features differ according to the anatomical position in the skin of the inflammatory changes, the particular organism concerned, its virulence, the resistance of the patient, and the severity and duration of the predisposing seborrhoeic state.

The problem is a difficult one, but I think that, clinically at any rate, we must draw a distinction between seborrhoeic dermatitis, whether occurring in the follicular petaloid form (flannel rash) or as a scaly dermatitis (eczematide), and what I term true seborrhoeic eczema.

My view at present is that we must recognize three distinct conditions: (1) seborrhoeic dermatitis due to infection of the skin with a *Staphylococcus albus* or *aureus*; (2) primary acute seborrhoeic eczema due perhaps to irritation of the skin produced by some acid substance taken up by the epidermal cells; (3) infective eczematoid dermatitis due to sensitization of the skin to pyogenic organisms having occurred, and probably, not always although usually, associated with the seborrhoeic state. This may supervene in either 1 or 2.

The Urine in the Acute Seborrhoeic State.

It is in cases of the acute seborrhoeic state with acute or recurring attacks of seborrhoeic eczema or dermatitis that I have carried out most of my investigations with Drs. Ryffel, Joffe, Grace, and Payne. As I pointed out in the original paper written with Dr. Semon, these cases show increased alkaline tolerance often to an extraordinary degree—that is to say, large doses of alkali may have to be given before the urine becomes alkaline. This fact has been observed in a large number of cases met with since the war, not only among out-patients, in whom, of course, one cannot be

absolutely certain that the dose of alkali prescribed has actually been taken, but also among patients in hospital in whom the amount taken is accurately known, and whose urine can be examined daily.

Dr. Ryffel has kindly investigated the urine of several of my cases with a view to determining the ammonia ratio, and what may be termed the acid ratio. The former is, of course, the ratio of nitrogen excreted as ammonia to the total nitrogen, and is very high in diabetes; the latter is the acidity of the urine expressed in the same terms as the ammonia ratio. A survey of his figures shows that in these cases both the ammonia ratio and the acid ratio tend to be higher than normal, sometimes very markedly so, and the sum total of the two ratios is almost invariably high.

The question naturally arises whether the alkali in these cases is absorbed. In order to test this point Dr. Payne kindly investigated the faeces of one of my patients who was taking very large doses of alkali, and he found that their mineral content was not above normal figures, showing that absorption had taken place. We may therefore consider it established that in probably the majority of cases of the seborrhoeic state in its severe or acute form there is diminished alkali reserve, often to a very striking degree.

The Blood Sugar in the Seborrhoeic State.

Dr. W. H. Grace, working in my department at Guy's Hospital, carried out some investigations on the sugar content of the blood four or more hours after a meal in certain skin diseases, using the Folin-Wu method of determination, and comparing the results obtained with numerous controls. He found that in cases of acute seborrhoeic eczema or dermatitis, uncomplicated by septic infection in the form of boils, pustules, or abscesses, the sugar content of the blood was not as a rule much above normal, the average figure being 0.116 per cent. In chronic cases, however, in which secondary pyogenic infection had occurred the figure was much higher, averaging about 0.2 per cent., and in some cases reaching 0.28 per cent. It was found that the improvement in the condition of these patients proceeded *pari passu* with the fall in the blood-sugar content.

The Etiology of the Seborrhoeic State.

The chief underlying cause is, in my opinion, faulty digestion and metabolism of carbohydrate, and to a less extent, perhaps, of fat, whereby an excess of organic acid by-products is produced. These are apparently secreted through the sebaceous and sweat glands, causing not only excessive secretion, but also, of course, an alteration in the composition of the sebum and sweat. It is probable, too, that these acid products are taken up by the cells, not only of the glands, but also of the whole epidermis and mucous membranes, and are combined with or dissolved in the fatty substances in which these cells are so rich. At any rate, as Darier suggests in his description of "la kéruse," there is presumably an alteration in the chemical composition of the epidermal cells which produces a modification of the process of keratinization, and diminishes their resistance to bacterial infection, probably by affording the bacteria a more suitable medium for active growth.

Once the bacteria—staphylococci and the acne bacillus—become established another factor comes into play—namely, bacterial sensitization or snceptibility, which is not confined merely to the skin, but affects the system as a whole.

The origin and nature of the acids responsible for the diminished alkali reserve and the high ammonia ratio in the seborrhoeic state probably result from the improper digestion and incomplete oxidation of carbohydrate and perhaps fat. The evil effect of an excess of sweets, cakes, pastries, etc., in patients with acute or seborrhoeic eczema and dermatitis is well known clinically, and in my opinion the chief factor in the production of the seborrhoeic state is the taking of an excess of soft carbohydrate foods and their imperfect digestion and oxidation. The diet of a large proportion of our population of both lower and upper classes is hopelessly unphysiological, especially in large towns. The tendency is to take an undue proportion of soft, concentrated carbohydrate food, which cannot be masticated and which is far in excess of the needs of a person living a sedentary life, very often in overheated, imperfectly oxygenated surroundings. On the other hand, fresh green vegetables and fruit, which supply a maximum of alkaline salts and a minimum of nutriment, are taken sparingly or not at all by many people. Some, too, not only take an excess of carbohydrate but devour large quantities of meat as well. I am in the habit now of asking

many of my patients to write down everything they eat during a period of three or four days, and their resulting diet sheets are often amazing.

Treatment.

I will conclude by considering the treatment of the seborrhoeic state, the principles of which are based on the etiological factors I have suggested. In its acute form, which may be associated with primary seborrhoeic eczema, the administration of large doses of alkali without any local treatment is specific. When sufficient alkali has been given the flushed appearance and the hypersecretion of the sebaceous and sweat glands disappear, and the eczema, if present, dries up. Moreover, the patients confess to a feeling of well-being, their appetite returns, and the sensation of heat and itching in the skin is lost. In the chronic form of the seborrhoeic state, in which bacterial infection has become established, producing clinical seborrhoeic dermatitis, acne, sycois, etc., the problem is not so simple, for bacterial sensitivity has become a superadded factor, and is often the more important. Treatment then consists in regulating the diet as one would in a mild case of diabetes, in insisting on regular out-of-door exercise, in ensuring a sufficient intake of alkaline salts by giving plenty of fresh green vegetables and fruit, and, if necessary, by administering sodium bicarbonate before meals; in removing any septic condition of the mouth and throat, or a focus such as a chronically inflamed appendix; in prescribing full doses of hydrochloric acid after meals if there is hypochlorhydria or achlorhydria, as there is in most cases of rosacea, and in giving an autogenous vaccine prepared from the infecting organisms. Local treatment in these cases is, of course, of great importance, and its rationale is to render the skin dry by means of sulphur, salicylic acid, resorcin, the mercurials, and the x rays. But unless the diet, the digestion, and the mode of life of the patient are regulated, relapse is almost certain to occur when the local treatment is discontinued. With regard to vaccine treatment, I am aware that many observers of greater experience than my own are unconvinced of its value. It is probable that chemotherapy by preparations such as colloidal manganese and stannoxyl may eventually take its place, but till then I shall remain one of its strongest advocates. It must, however, be controlled by serological tests, it must be given intelligently, and it must be combined with rational treatment of the underlying pathological state which has led to the lack of resistance to the infecting bacteria. I believe that the unfavourable opinion that has been formed by many dermatologists of the value of vaccine therapy in infective conditions of the skin is due partly to the use of stock vaccines, which I have now entirely abandoned; partly to the fact that the specificity of the organisms isolated is not determined by serological tests; that the dosage is injudiciously planned—for it is easy to make a condition worse with vaccines—and that the injections are not persevered with long enough; and partly that the underlying factors, which have lowered the patient's resistance to infection, are neglected. In some chronic cases of infective eczematoid dermatitis and of generalized seborrhoeic dermatitis, which are often accompanied by boils and hidradenitis, I have found all treatment unavailing until an autogenous staphylococcal vaccine was given, whereupon steady improvement began and continued until a cure was obtained. In some of these stock vaccine had been given without effect. In spite of all arguments to the contrary, my clinical experience has convinced me of the specificity of vaccine therapy, and, until we can find infallible methods of chemotherapy against the various types of infecting organisms, I believe that specific vaccination will continue to be the method of choice rather than non-specific protein therapy.

DISCUSSION.

Dr. R. W. MacKENNA (Liverpool) expressed the pleasure the Section had derived from listening to the two opening papers. He agreed with the remarks made by the President in introducing the discussion that the results of the frontal attack upon the question of seborrhoea and the seborrhoeides had been somewhat unproductive of definite results; but he believed that the flanking attack made by Dr. Barber and his colleagues on the question, along the lines of biochemistry, was likely to be much more fruitful. He paid a compliment to the work done by Dr. Barber during recent years—work which was likely to leave a permanent mark on dermatology.

activity of the sebaceous glands, which was a necessary antecedent to all the skin lesions classed as seborrhoeic dermatitis and the seborrhoeides, depended on some stimulation by the secretions of the endocrine glands. But the oversecretion alone was not everything. There was some other factor, and that factor was probably a micro-organism of some sort. When he read Dr. Barber's and Dr. Semon's original paper on the seborrhoeic state he was of opinion that they had made an illogical and unwarranted deduction from the facts before them; for it was unsound reasoning to conclude that over-elimination of acid in the urine told us anything about the alkali reserve in the body. Overacidity of the urine might mean simply overproduction of acid, and equally rapid elimination in order to keep the alkali reserve normal. Dr. Barber's paper that day, however, embodying the results of his later researches, proved that his (Dr. Barber's) original deduction was correct—namely, that in seborrhoeic conditions there was a definite lowering of the alkali reserve, and, coincidentally, an increased alkali tolerance. He did not agree with Dr. Cranston Low's theory as to the retention of their hair by women. It depended, he believed, on endocrines secretions. As Sabonrand long ago pointed out, eunuchs never go bald. With regard to protein sensitization in the skin he agreed with Drs. Low and Barber that the possibility of its place as a factor in the production of seborrhoeic dermatitis should not be forgotten; but he thought one should go warily in using protein sensitization as an explanation of all dermatological conditions of obscure cause.

Dr. KENNETH WILLS (Bristol) said that emphasis should be laid upon the infective nature of pityriasis capitis. He had found from clinical observation that eczema seborrhoeicum ran in families, and that it was directly conveyed from parent or nurse to children. It was caught on the parts of the skin exposed, and might spread from those inoculation points. The primary lesion was a plugging of the follicles, followed by circumfollicular erythema with itching. Subsequently, rubbing and scratching led to "eczematization." The same observations might be made in adults, where the cocci were conveyed from a scurfy scalp by scratching. Thus an insect bite or other simple itching lesion might become infected with eczema seborrhoeicum.

Dr. DOUGLAS HEATH (Birmingham) said that he also had noted that large doses of alkalis improved acute seborrhoeic conditions, and he had also found that sulphur lotion was much improved by being made up in alkaline solution. Olive oil, although a popular remedy, he considered was very deleterious to seborrhoea. He had obtained good results in the treatment of acne from the use of a mixed vaccine.

Dr. A. M. H. GRAY (London) asked the meeting to define what was meant by seborrhoea, seborrhoeic dermatitis, and seborrhoeic eczema. He considered seborrhoea to be a mere excessive secretion of the sebaceous glands; he excluded from it conditions where there was any inflammation whatever. Seborrhoeic dermatitis he called those cases where there was some inflammation, the most typical of which were the cases of circinate and figurate dermatitis in the centre of the chest and back, also pityriasisiform conditions of the scalp. In both of these bacteria, but of doubtful nature, were concerned. He refused to associate premature alopecia with the barber's shop and local infection; in the present state of our ignorance of the endocrine glands he preferred to stress the hereditary factor in these cases.

Dr. NORMAN WALKER (Edinburgh) believed, on the contrary, that the local cause was responsible for the loss of hair. He believed in frequent washing of the scalp as a preventive of baldness, and in the treatment of the scalp as the key of all the treatment of seborrhoeic conditions, and above all of rosacea. He also emphasized the importance of treating oily seborrhoea of the scalp when treating acne vulgaris. He referred to the importance of dermatoses, especially scabies, in war.

Dr. O'DONOVAN (London) referred to the frequency of hyperglycaemia in connexion with inveterate sycois, but found that the exhibition of alkalis was of no therapeutic value. He had got the best results in bad sycois from painting with the liquid acid mercury nitrate, which was painful but effective.

Dr. F. ANDERSON MURRAY (Glasgow) said that the question of treatment of seborrhoea and seborrhoeic dermatitis was

had been paid to the preventive treatment of seborrhoea. He thought that the scalp was frequently infected in childhood, and should be treated accordingly. Later in life the condition frequently was a question of occupation. Diet was also of considerable importance: patients prone to the condition should be sparing in the use of starch and sugar.

Dr. W. H. BROWN (Glasgow) referred to two cases in which gastric analysis showed great hyperacidity. Dr. LANCASHIRE (Manchester) also emphasized the importance of the preventive treatment against seborrhoea during childhood. He said that in local treatment he got the best results from sulphur in the form of ointments. He had been disappointed with colloidal sulphur.

Dr. J. GOODWIN TOMKINSON (Glasgow), in view of the conflicting theories as to the causation of seborrhoea, hesitated to dogmatize. He was, however, strongly inclined to accord a very important part to the microbacillus of Sabouraud. It was known that in some instances it might be present in the skin without causing any apparent modification in secretion, but its constant presence in teeming numbers in the cocoon was, to say the least, suggestive. This raised the question of contributing factors—factors which elicited or determined the pathogenic facilities of the microbacillus. On the one hand, these might be internal, on the other local, due possibly to the symbiosis of two or more members of the cutaneous flora. Among the internal causes one connected with the maximal manifestations of seborrhoea was puberty, which was associated with great glandular activity. Again, there were other adventitious internal conditions known to aggravate the eruption of seborrhoeides. It was well known that overwork sometimes determined an outbreak of seborrhoeic dermatitis. He had had a striking instance of this in his own practice about two years since. A medical student, long the subject of seborrhoeic dermatitis in the presternal region, had had the misfortune to fail in his final examination and had been unduly depressed thereby. He had also been unduly addicted to sweetmeats. When seen by the speaker he was confined to bed and feverish, and his skin was in a condition of generalized exfoliative dermatitis.

The President (Dr. LESLIE ROBERTS, Liverpool) said that the conclusion arrived at as to the nature of seborrhoea depended on the point of view taken by the investigator. Clinical investigation carried them but a little way. There were two main lines of promising research: (1) that of the comparative microscopical anatomy of the vertebrata; (2) the biochemical method. The comparative anatomical method brought to light a remarkable correlation between the pilogenetic and sebaceous functions of the follicles. In the fulfilment of both these functions cells were cast off bodily. The follicle was, in fact, a primitive moulting organ, in the exercise of which function the clinical manifestations were strikingly different—namely, alopecia or baldness, or the arrested development of hair, as in the lanugo hairs, coupled with an increased output of fat-laden epithelial cells. Alopecia areata was the most complete example of the seborrhoeic or moulting process. In birds and reptiles in which the keratin-laden cells amounted to an exoskeleton, the sebaceous glands were either entirely absent or were gathered together into a single gland mass situated at the root of the tail of most birds, or were remarkable for the paucity of their numbers. The same correlation was observed in the human skin in the palms and soles, where some approach to a horny exoskeleton was found. If the true fat glands of the skin were looked upon as organs for the secretion of fatty acids, then the true fat glands of the mammalian skin were the sweat glands which found their highest development in the mammalian milk glands. The biochemical line of research would probably carry them farther into the heart of the subject than the anatomical. Dr. Barber and his collaborators had done useful work on those lines. They had ascertained experimentally certain facts which confirmed the opinion of Darier and others that the moulting process of keratin and fat cells was associated, and indeed was the outward manifestation of a chemical condition of the tissue fluids which seemed to consist, in part at least, in a lowering of the basal salts. Dr. Barber and Dr. Semon had demonstrated an increased alkaline tolerance in severe cases of seborrhoeic dermatitis. The interpretation of the biochemical data was, however, extremely difficult, and before this observation could be definitely established as a general truth it was necessary to ascertain whether lowering of tissue alkalinity and

increased acidity of the urine was not a natural accompaniment of all cutaneous and visceral inflammations. It had been shown to accompany erysipelas and pneumonia, and the question arose as to whether the hypo-alkalinity of the tissue fluids was not due to the withdrawal of basic salts from the blood, and in reality had no connexion with the seborrhoeic process itself. This must be left for future investigation to decide.

The question of blood sugar was one of great practical importance in relation to inflammation of both the skin and the viscera. That its presence in the inflamed tissues was inimical to recovery was well established, but it was necessary to differentiate between the saccharides. Taking glucose as a typical monosaccharide, it had been shown by Folin and Berglund that the ingestion of 200 grams of pure glucose did not raise the level of the blood sugar above the renal threshold of glucose secretion. There was reason for believing, as Folin and Berglund had pointed out, that the absorption and excretion of foreign unsuitable carbohydrate material present in grain, vegetables, and fruit was of daily occurrence; and to this must be added the decomposition products due to cooking, canning, and baking of the food. There was, so far as we knew, no mechanism in the digestive tract for preventing the absorption of these soluble but incompletely digested carbohydrates. These authors further suggested that foreign carbohydrates played an important part in the etiology of many obscure skin and joint troubles. But we were going farther than the evidence warranted if we assumed that they were essentially connected with the seborrhoeic or moulting process. Turning to the clinical side of the seborrhoeic dermatoses, it was bound to admit that the group was vague and ill defined. All inflammatory reactions which were frankly connected with the moulting process could be rightly called seborrhoeic. These included the dry, discoid or circinate infiltrated, hyperaemic patches met with on the front of the chest and on the back. The eczematization of the scalp coexisting with the loss of hair and increased output of sebaceous material must also be included in the group, and this form in many cases showed a tendency to spread downwards behind the ears, and to appear in the bends of the elbows and groins. In the worst forms of severe "seborrhoeic dermatitis" described by Dr. Barber it was probable that an emotional factor played a considerable part in determining the form and distribution of the disease.

Dr. CRANSTON LOW, in his reply, again emphasized the necessity for a revision of the nomenclature, and said that there would always be confusion until the term "seborrhoea" was only used in its true sense. He referred again to the cutting of the hair as the cause of common baldness. In races such as the Cingalese, where the men all wore the hair long, baldness was practically unknown. Dr. Low also sounded a note of warning with regard to the inferences to be drawn from the biochemical changes in the blood and urine in seborrhoeic conditions, and suggested that these changes might be the result and not the cause of the skin condition.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

MELANOTIC SARCOMA OF CHOROID AND OVARY.

MELANOTIC sarcoma appears to be accepted as the most virulent form of malignant tumour on account of the early date at which it forms secondary deposits in other parts of the body. For this reason, and because the literature on this subject is meagre in quantity and lacking in details, I venture to describe a case which shows some interesting features.

Mrs. M. is now 38 years of age and, with the exception of minor ailments incidental to an overstrung nervous temperament, and severe eclampsia previous to the birth of her second baby seven or eight years ago, has enjoyed fairly good health. She has worn an artificial right eye for many years, her explanation being that the sight failed in her right eye in August, 1906, and after a course of medical treatment (during which sixty consumes!) the eye was removed on April 1907. "The tumour"—she being then 23 years of age.

In September, 1921, she consulted me about a small lump she had noticed under the skin of the right upper arm near the anterior border of the deltoid muscle. The skin being thin and fair the tumour showed almost black beneath. I excised a dead black lobulated growth the size of a horse bean. On microscopical

examination it proved to be a typical spindle-celled melanotic sarcoma, melanin permeating the cells as well as being intracellular. In view of the fact that her eye had been removed fourteen years previously I obtained from Mr. Collier Green, who performed the operation, the information that there was a small tumour of the choroid close to the ciliary region, which on examination was pronounced to be a pigmented spindle-celled sarcoma. I thereupon made a complete examination of the patient and found another subcutaneous tumour in the middle of the back near the fifth or sixth dorsal spine, and *per vaginam* a tumour the size of an orange—whether uterine or ovarian I could not determine. Mr. H. T. Hicks, gynaecological surgeon, was called in consultation, and advised early removal of the tumour. This was carried out on October 3rd. The subcutaneous growth in the back was first excised and was found to be similar in all respects to the one I removed from the arm. The pelvic tumour was ovarian (left), the size of a large orange, glistening black and lobulated, solid with the exception of a small cyst containing dirty black fluid. The section was dead black. The right ovary was apparently healthy, but it was deemed advisable to remove it.

The pelvic glands did not appear to be involved and other organs were apparently normal. On microscopical examination both growths proved to be spindle-celled melanotic sarcomata.

Recovery was complicated by cerebral symptoms suggesting thrombosis; the patient lay in a restless and semi-unconscious state for two or three days. This slowly passed off, and in a few weeks' time she had more than regained her usual health; in fact, all her friends tell her she has never looked so well. She has put on weight and has a nice rosy colour in her cheeks. No sign of recurrence could be found at a complete examination on March 29th last; this I am going to repeat again shortly.

The interesting features are, first, the long time which has elapsed between the first onset of the disease (the primary growth of the choroid) and the appearance of secondary growths in the skin and ovary—namely, fourteen years; this is all the more striking as a failure of sight was noticed eight months prior to the enucleation of the eye. Secondly, the absence of lymphatic gland involvement. Thirdly, the absence of any further trouble nine months after operation.

Derby.

LUPUS ERYTHEMATOSUS TREATED BY DIATHERMY.

From time to time cases of lupus erythematosus treated by diathermy are recorded, but in all cases fulguration appears to be the method adopted. As a different method was employed in the following case with a satisfactory result, the notes may prove of interest.

Mrs. S., aged 35, was sent to me by Dr. W. B. Mackay, C.M.G., of Berwick, on February 25th, 1921, who asked me to try the effect of diathermy. About five years previously she had noticed a small red itchy spot on her nose during the winter. It disappeared during the warm weather, but reappeared the following winter, and since then had gradually become larger. Dr. Mackay was then away serving in the army, but she received treatment without relief, and was seen by a well-known dermatologist in another town, who diagnosed lupus erythematosus, and prescribed for the condition, which, however, proved obstinate.

When I saw her first the lower two-thirds of the nose were affected. Gauze dipped in saline was placed over the nose, and a soft metal pad moulded over it. The current was then turned on, and gradually increased to as much as she could bear, the idea being to get a vigorous reaction, but to stop short of burning. She was told to say when the heat became severe, but in spite of this and of frequent inspections a small burn appeared. The current used was 500 to 600 milliamperes. Owing to various causes she was unable to return till May 5th, when there was a considerable improvement in the condition. The burn, which had been superficial, had healed with very little scarring. On this occasion the current was kept at about 300 milliamperes, and switched off whenever she complained of the heat. Improvement again occurred. After a third application the nose was normal in appearance, and the patient, who previously was very unhappy about her disfigurement and had avoided mixing with others, was much brighter and was going about much more.

About the end of November a very small red itchy point reappeared. This was again treated three times, and from the middle of January was not visible, but two further applications were made, one in February and one in March. Two months later she again came to see me as she felt a little irritation, and though nothing was the result of the application was given. I saw her again a few days later, and she appeared in every way normal and healthy. I hear that she is free from any return at present.

Each application took from twenty-five to thirty minutes, and the nose was inspected frequently lest any burning occurred. After each treatment the nose was very red and swollen for a few days.

I have not seen any mention of this method being used before, but think that applications at shorter intervals than it was possible to give in this case would be better.

Surgeon, Ear, Nose and Throat Hospital, Newcastle-on-Tyne.

Reports of Societies.

THE PROBLEMS OF ASTHMA.

THE Section of Therapeutics and Pharmacology of the Royal Society of Medicine held its first meeting of the session on October 10th.

Dr. W. LANGDON BROWN, in his presidential address on the problems of asthma, said that in pursuance of his conception of the functions of the Section he had chosen as his subject one which had both clinical and experimental aspects. The problems of asthma were for years most baffling, but recent work had cleared the ground and defined the issues. Those problems had now revealed themselves as involving subjects of most topical interest—psychotherapy, sensitiveness to foreign proteins, vagotonia, and endocrine balance. The treatment of asthma summarized in itself, as it were, the chief trends of modern therapy. But there had been a tendency on the part of enthusiastic workers in some one of those fields to neglect due consideration of the other aspects: successful treatment implied recognition of them all. It was always a dangerous thing to try to express a disease in a formula. Nevertheless, he attempted to do so for asthma not long ago. Hurst had recently improved upon that formula, and he accepted his emendation gladly. Hurst had defined asthma as due to an unstable or irritable condition of the bronchomotor portion of the vagus nucleus, which caused it to react unduly to psychical or peripheral stimuli, or to foreign proteins in the circulating blood. He (the President) thought that this could still be modified with advantage by including the obvious vasomotor turbulence which accompanied the bronchomotor spasm, as it was always present and was sometimes the most striking feature of an attack, just as it was in the closely allied condition of hay fever. Moreover, it was carried out by the same vagal mechanism. Thus modified, the formula could be expressed diagrammatically by the accompanying figure.

He would first consider the stimuli acting on the centre and then some features of its response.

Psychical Stimuli.—That asthma often occurred in neuro-pathic families and that asthmatics were unduly suggestible were well-known facts. The paroxysm excited by an artificial flower figured in every textbook. But it was extraordinary to witness the almost instantaneous relief that might follow a hypodermic injection of distilled water into a patient who was anticipating one of adrenaline, when that was known to be efficacious. It made him wonder how much of the success of single minim doses of adrenaline was due to suggestion and how much to the drug. At any rate, it explained why the asthma curer who had profound belief in the efficacy of his treatment found increasing justification for that belief; for his confidence aroused responsive confidence in his patient. But what was not so clearly recognized was that the effective stimulus often arose from a psychic conflict. Such a conflict might express itself at the psychic level of the nervous system as an obsession or a phobia, and at the sensorimotor level as a paralysis, a tic, a contracture, or an anaesthesia; while if it sank deeper to the visceral level it might express itself as glycosuria, exophthalmic goitre, or asthma. Naturally, other influences would help to decide which of those ways the psychic trauma revealed itself. Thus one sufferer from a psychic conflict who had to face a hostile environment might escape through an hysterical paralysis, but another who had to face the internal disorder produced by sensitiveness to foreign proteins was more likely to develop asthma.

Peripheral Stimuli.—Dr. Langdon Brown said he had little to add to the common stock on this subject. The influence of eyestrain, hay fever, and other nasal troubles, sinus infection, gastric and intestinal disturbances, and of uterine disorders was well recognized. But he would like to call special attention to enlarged bronchial glands, especially in children, and to suggest that that might explain the liability of healed tuberculosis to excite asthma in susceptible subjects. Interesting observations by Baccarini showed that peripheral irritation of the pleura, such as paracentesis, might excite an attack of asthma. In the epileptic

a fit could be similarly produced, which led Baccarini to compare bronchial spasm to a localized epilepsy. Other points of resemblance between epilepsy and asthma would readily occur to one.

Foreign Proteins.—Of recent years great attention had been paid to this factor. Morley Roberts had made the profound remark that immunity was assimilation. There was one flesh of birds and another of beasts. From the welter of amino-acids which resulted from the disintegration of food proteins each animal had to build up its own characteristic and specific tissues. Specificity was chemical as well as morphological. To some foreign proteins a man was naturally immune—that is, he could assimilate them automatically; to others he acquired an immunity—that is, he learnt to assimilate them. But to some foreign proteins immunity was neither congenital nor acquired. The tissues continued to resent the intrusion of such proteins: they would not assimilate them. Such proteins excited anaphylaxis in varying degrees. Richet had defined anaphylaxis as the last stand of the race against adulteration of its protoplasm. In extreme degrees anaphylactic shock was fatal because assimilation would mean too profound an alteration of bodily structure. In less degrees anaphylaxis declared itself in violent attempts to get rid of the foreign invader. As Drury had expressed it, the toxic idiopathies were conservative and self-repairing mechanisms under parasympathetic control.

The Influence of the Parasympathetic.—The great function of the parasympathetic might be defined as promoting the assimilation of suitable and the rejection of unsuitable material. Thus it started the secretory and muscular processes of digestion, while it emptied the rectum and bladder, and could reject food by vomiting. The excitation of bronchial catarrh and cough was in like manner a way of ridding the body of unsuitable material, and it is interesting to recall here that drugs which were expectorant in small doses were emetic in larger ones. The similarity of the parasympathetic action on the alimentary and respiratory tracts was not surprising when one remembered that the latter developed as an outgrowth from the former. The vagal factor in normal respiration might indeed be defined as a mechanism for ensuring the alternate taking in of assimilable oxygen and the rejection of unnecessary CO₂. Confronted with an irrespirable gas, the vagus checked the entrance of this to the lungs by laryngeal spasm. But he did not think it possible to explain in that way bronchomotor spasm, which, while tending to interfere with elimination, did not prevent the entrance of unsuitable material. That, he thought, was an example of the exaggerated response so typical of pathological states. The undue irritability of the vagus centre set up such a strong efferent impulse that it was not confined to the vasomotor channels, but overflowed along the bronchomotor fibres. Without accepting the whole of Eppinger and Hess's theories, one might agree that the asthmatic was a vagotonic, and was liable to other manifestations of vagotonia. He recently had a curious instance of this in a man who suffered from both asthma and gastric ulcer, and who had found out for himself that he could relieve the pain of his ulcer by smoking a stramonium cigarette. And he (Dr. Langdon Brown) would agree with the description which had been given of a form of mucous colitis as "asthma of the colon."

The Sympathetic and Endocrine Balance.—But vagotonia might be relative as well as absolute. In other words, it might well be that an overacting vagus was due to diminished action of the antagonizing sympathetic. One of the ways in which the sympathetic carried out its defensive function was by activating those endocrine glands which flooded the blood with sugar, thus increasing metabolism and exciting a febrile response. Lest this excess of sugar should be wasted by overflowing into the urine the threshold of the kidney was raised in fever. But the febrile response was not the only way in which immunity was acquired. One of the greatest gaps in present knowledge was our almost total ignorance of the part played by the

Beyond the yield of ambocceptors, following anything was known on this point. Yet he felt that further research would show that just as anaphylaxis was associated with vagotonia the opposite condition of sympathicotonia was related to immunity through the endocrine system. Not infrequently hypo-adrenalism followed or accompanied anaphylaxis, and certainly adrenalin had a valuable action in anaphylactic shock. It had a similar effect in some cases of urticaria. Hurst considered that the toxic idiopathies, including asthma, produced their effect, at any rate in part, by depressing adrenal activity, and he believed that the influence of fatigue in inducing the asthmatic paroxysm was capable of a similar explanation. Morley Roberts suggested that so might the apprehensiveness so common in asthmatics be a factor. The overactivity of the broncho-constrictor fibres of the vagus was kept in check by the broncho-dilator action of the sympathetic, which the

secretion of adrenalin would stimulate. Hence the effect of an injection of adrenalin, or of sudden fright in checking an attack of asthma. Asphyxia had a similar action and produced the same effect, and was thus, no doubt, a factor in bringing the attack to an end without a fatal issue. Stewart and Rogoff, it was true, denied this emergency action of adrenalin; but Cannon's recent experiments had disposed of much of their purely destructive criticism. The liability of asthma to come on during sleep, when the parasympathetic gained the upper hand, further pointed to the influence of disturbed balance between the two great branches of the visceral nervous system. The reinforcement of the adrenalin effect by pituitrin might be held to point in the same direction. The glands which co-operated with the sympathetic appeared generally to help in checking the asthmatic paroxysm. The stimulating effect of the gonads in the sympathetic-endocrine group might account for the influence of uterine disease in exciting asthma. It must be admitted however, that it was difficult on this hypothesis to explain why asthma was liable to appear at puberty and to be aggravated by pregnancy, when the thyroid and pituitary were stimulated, unless it was that some asthmatics had a gonadal deficiency which declared itself in that way. Certainly gonadal deficiency might be associated with thymic asthma, which was comprehensible, since the thymus was an infantile organ, apparently antagonistic to the gonads. In general terms, it would appear that when the endocrine balance swayed in the direction of the vagus, asthma was likely to occur in susceptible subjects; when the balance was redressed in favour of the sympathetic, attacks might be cut short or prevented.

Asthma, Anaphylaxis, and the Skin.—The skin undoubtedly has excretory functions. He recently had a severe and ultimately fatal case of uraemia, which first manifested itself by a pronounced toxic erythema. Urea was greatly increased both in the blood and cerebro-spinal fluid, while in the latter other amines were demonstrated to the extent of 0.24 per cent. The rashes of the exanthemata had often been compared with that produced by serum in anaphylactic subjects. This idea of an excretory mechanism found expression in the popular notion that it was good to "get the rash out." The toxin which could not be assimilated—that is, to which the body was not immune—must be got rid of somehow, and a any rate removed from the vital structures. Here it was interesting to note the occasional alternation of attacks of eczema and asthma. The following family tree which came under his own notice was a striking example of this alternation in different members of the family.

The condition of laryngismus stridulus was recognized as the infantile equivalent of asthma. It was further of interest to recall that both in skin diseases and in asthma eosinophilia was a usual feature of the blood picture. As an attack of asthma went on and expectoration became more abundant the eosinophiles passed into the sputa. He should regard the skin reaction of an asthmatic to foreign proteins as an attempt to wash out the offending non-assimilable material from the skin. He was proceeding to look for the occurrence of eosinophilia in the urticarial wheals produced by this test when Dr. Mackenzie Wallis informed him that he had already observed it. He thought that that all accorded with his observations of Kanthack and Hardy, thirty years ago, of the part played by eosinophilia in bactericidal infections, an intestinal digestion, which had passed into undescribed oblivion.

A Rational Basis for Treatment.

Such considerations as these helped to provide a rational explanation for some methods of treatment which had been empirically used in the past. He hoped also that they might help to co-ordinate the views of those working at different aspects of the problem, and to emphasize the necessity for all-round assault on every case of asthma from those various aspects. For some, asthma was merely a psychological problem; but that was to close one's eyes to the toxic factor. For others, the toxic element was the primary thing, the nervous factor being merely the failure of the nervous system to co-operate successfully in getting rid of the toxin. The view had been well expressed by Morley Roberts thus:

"Why is there a spasm? What is the spasm but violent overacting surface tension pulling every cell in the small bronchi an alveolar spaces into its least form, as it tries to squeeze on irritants—tries to defaecate, so to speak. The sympathetic an

parasympathetic rush in to aid. There is a tendency to overrate nervous action. Cells live their lives, have their disasters, even without nervous interference except in stress, as they did in the beginning."

But that view was not capable of explaining the influence of suggestion in actually producing a paroxysm in the absence of the exciting toxin. The suggestibility of the patient should be utilized to help him confidently to expect a cure. The effect of climate might often be due to suggestion. An asthmatic went to a place and had an attack; therefore, each time he went there he expected to have one, and had it. The converse was also true. To point that out in the former instance might help him to avoid repetition. But search must also be made for deeper-seated psychological troubles. Naturally, sources of peripheral irritation must be eliminated; that included avoidance of late suppers and cold bedrooms. The skin reactions, in his experience, were very helpful in determining the foreign proteins to which the patient was sensitive. Not only in asthma should that be tried; it was worth trying in any vagotonic with toxæmic symptoms.

He recently had under his care a patient who was emaciated and profoundly depressed, but whose chief objective trouble was a painful swelling of the tongue and lips. Dr. Mackenzie Wallis tested his skin reactions and found him highly sensitive to cereals. In addition to other simple measures, cereals were removed from the diet, and he was allowed many things which had formerly been prohibited in the belief that he had gout. The effect was dramatic; in one month he put on 16 lb. in weight. Only a day ago he received a letter from his medical man, in the course of which he said, "I think his almost daily progress has been one of the most marked and interesting cases I have had under my observation for a long time. Socially he is entirely altered . . . bright and entertaining, and his old-fashioned courtesy has returned. In fact, he is so far a complete revolution and revelation."

An experience like that made one think seriously of the toxic factors which must often be overlooked in cases diagnosed as neurasthenia or "functional." Where the offending protein could not thus be eliminated, one should consider what methods of desensitization were feasible. He would like to add that in his experience it was most important to exclude the syphilitic toxin as the offending protein. The universal belief in the efficacy of the belladonna group in asthma found its justification in the paralyzing action of such drugs on the parasympathetic endings, just as the filip given to the sympathetic by adrenaline or cocaine helped to redress the balance in another way. According to some the influence of iodide was mainly to activate the thyroid; if that was so the benefit of this drug in asthma was comprehensible, since the thyroid secretion lowered the threshold to sympathetic stimulation. But so far there was no explanation of the way in which arsenic acted in this disease, though certainly it often seemed to help. The importance of doing everything one could to restore an impaired endocrine balance was, he thought, undoubted. In conclusion, an all-round attack on the problems of asthma seemed to him to afford the best chance of relief, especially if carried out before structural changes such as emphysema had occurred. After that a vicious circle was set up which it was hard to break.

Discussion.

Dr. FRANK COKE thought that medical men were in great danger, in dealing with asthmatic cases, if they looked upon any of them as being certainly cases which were psychic and possibly neurasthenic, and so forth. A gentleman came to him from one of the nerve specialists, and it was rather a question whether he was not going to have general paralysis; he was very peculiar in a great many ways. On his skin being tested he was found to be sensitive to nothing else but potatoes. The removal of them from the diet had an effect exactly like that in the case mentioned by the President; the patient was now perfectly normal and contented in every way. The question of locality and so forth was important. A small boy who had asthma at home was sent to him. He went to stay with five different aunts and uncles; with three of them he had asthma badly, and with two of them he was perfectly free. At places which were particularly healthy he had asthma very badly. On the boy being tested he was found to be sensitive to dog hair. Another case was that of a lady who was perfectly free from asthma for six months until she went to the seaside. On the first night she developed asthma. It was found that the quilt over her bed was covered with dog hair; that was obviously the cause of her asthma; it was taken away and the asthma went immediately. The influence of the proteins was astonishing. A negro who gave only a +1 reaction to hen feathers became free from asthma, but had it again as soon as he moved his lodgings and slept on a feather pillow. As to the balance between the sympathetic and the vagus, that

subject was too deep to be touched upon on the present occasion; but he thought every case should be tested with the proteins.

Dr. H. CRICHTON MILLER wished to underline one point dealt with by the President. In dealing with asthma one was dealing on the endocrine side so notably with adrenal instability, and on the emotional side one was dealing equally notably with fear complexes. It was more especially the fear complexes that on the emotional side contributed to the asthmatic condition. The connexion between those two sides seemed to him too important to be lost sight of. It being a gland that was naturally mechanism all through the at paroxysm was attributable in some degree to an inability to cope with fear. That was putting the matter very widely indeed. How far any sensitization, any failure to immunize the organism against poison, might or might not render the individual less capable of dealing with fear, was a point which had to be cleared up in each individual case by such tests as those described by the previous speaker; but even then the medical man would still have in his hands an individual whose capacity for dealing with all the fear emotions was inadequate. That was one reason why mucous colitis and asthma were associated in the same kind of people. In both there was the same series of emotional failures, and also, he thought, the same series of endocrine failures.

The PRESIDENT, in answer to a question, said that the British habit of sitting in front of a fire during the evening and getting thoroughly baked and then going up to a cold bedroom ought to be avoided by an asthmatic. The great changes of temperature so common in houses without some kind of central heating were harmful.

Dr. C. O. HAWTHORNE expressed his appreciation of the very thoughtful suggestions contained in the address. It was obvious that within recent years medical men had been passing into a new phase in connexion with asthma. Numerous questions, both pathological and clinical in their nature, had been raised. The hopeful feature about the suggestions which had been offered in the address seemed to him to be that they were proceeding now to deal with causes of symptoms which before were regarded as diseases and treated in an empirical fashion; in other words, a case of asthma had become, not an opportunity for a label and for a more or less traditional prescription, but an opportunity for a specific investigation of the individual patient, with a view to determining the causation in the patient and to treatment based upon causation.

Dr. A. LAPHORN SMITH said that he was especially interested in the relation of eclampsia to asthma. He was quite sure that both eclampsia and asthma were due to poison in the blood. He asked whether people who were heavy meat eaters and who did not take much oxygen to burn the meat up were more liable to asthma than were vegetarians or fruit eaters. It had been his experience that they were. He had found remarkable benefit, not from putting more poisons like belladonna and stramonium in, but from eliminating the poison which was present. The best drug he had met so far was potassium bicarbonate. He had rarely found that a patient did not get better if he persisted for several weeks in taking two or three drachms a day of potassium bicarbonate, with perhaps a little lemonade. He would like the members of the Section to try the alkaline treatment of the spasm of asthma, as he had tried very largely the alkaline treatment of the spasm of eclampsia.

The PRESIDENT in a brief reply expressed his thanks for the very kind reception given to his address. With regard to Dr. Coke's remarks about locality, he had been rather impressed by the case of a medical man (an asthmatic) who told him that, having had an attack of asthma in a particular place, and having occasion to sleep there a second time, he felt sure he was going to have an attack, but said to himself, "This is merely a question of your getting the idea that you must have an attack if you come to this place. There is no real basis for it, and you will not have an attack." And he did not. He had been to the place repeatedly since and had not had an attack. With regard to Dr. Laphorn Smith's point about meat, he imagined that patients who were affected in the way described would be found by Dr. Coke's tests at any rate to be unduly sensitive to some form of meat protein.

ARTIFICIAL PNEUMOTHORAX.

A MEETING of the Cardiff Medical Society was held on October 10th, the chair being taken by Mr. W. MARTIN. Dr. PARRY MORGAN read a paper on "Artificial pneumothorax in the treatment of pulmonary tuberculosis." He pointed out the unanimity with which those who expressed their views on treatment in the report of the Medical Research Council's Committee praised this treatment, but noted that

there was not the same unanimity regarding what were suitable cases. Some advocated it only as a last resort—an extraordinary attitude towards an admittedly successful method of treatment. He gave reasons for the limited application of the method, and thought that the treatment should be commenced earlier than was usually the case. Complete collapse was not then necessary, for the gas in a partial collapse gave differential rest to the affected inelastic part of the lung, while the normal portions continued to expand freely as before. He compared artificial partial pneumothorax with the spontaneous collapse due to fluid or leakage from the lung, and pointed out that, although the collapse was temporary in these cases, it was often followed by good results. He argued that temporary artificial collapse might be expected to be followed by good results, and quoted recent publications to show that this was the case. These also showed that the objection to producing an early artificial collapse, that it was nearly always followed by adhesions, did not hold in the case of partial collapse, as adhesions did not as a rule follow, nor did fluid appear, provided the intrapleural pressure was always kept negative. The treatment, therefore, was applicable to both sides at one and the same time.

Dr. Parry Morgan also described the two manometer apparatus for performing the operation, and insisted that its alleged complication was more apparent than real. There were only two differences between it and the single manometer apparatus, such as that of Drs. Lillingston and Vere Pearson: (1) Instead of a clip to shut off the gas there was a contrivance by means of which the gas could be cut off very gradually; when this was done, the pressure in the manometer gradually fell from that in the reservoir to that in the pleural cavity, instead of being either the one or the other. (2) A second manometer was introduced, which merely registered the reservoir pressure, whether the gas flowed or not. He showed that the physical conditions obtaining in the chest could be reproduced by using a rubber-slopped bottle with the bottom cut out, filled with water, and inverted into a bowl of water. By means of this device he was able to demonstrate all the details of the operation, and to show clearly the advantages of the apparatus. From his demonstrations it appeared that no calculations were necessary.

Reviews.

MEDICINE IN THE WAR.

[SECOND NOTICE.]

LAST week (p. 691) we dealt with certain general considerations arising out of the first of two volumes on Diseases of the War, forming part of the *Medical History of the War*.¹ There remain to be dealt with the chapters dealing with the several diseases. There is a list of contributors at the beginning of the volume, but as many of the articles are joint compositions with the shares unapportioned it is sometimes impossible to ascertain which of the writers is responsible for particular statements.

The chapter on the enteric group of fevers contains interesting comparative records of other wars, which if they do nothing else indicate the supreme value of anti-typhoid inoculation. This point is further emphasized by the prevalence of paratyphoid A and B when the inoculation was against *B. typhosus* only and the corresponding decline when the triple inoculation was employed. In the discussion of the etiology very little new information is given; by no means can the presence of infection be avoided, but individuals can be rendered immune. Although this sums up the whole experience of the war, Wright, whose discovery made this immunity possible, is not mentioned either in the text or bibliography. The symptomatology and treatment is well summarized; there is little that is new, and there appear to have been no distinctive features in any of the theatres. Paratyphoid has received more particular study than ever before owing to the opportunities afforded by its occurrence apart from typhoid during the early part of the war. It is

stated, correctly enough, that to distinguish the paratyphoids from one another is impossible, and from typhoid, as a rule, difficult. The importance of recognizing the cases of paratyphoid that do not resemble typhoid and the difficulty of doing so are not made so clear.

The dysenteries are admirably dealt with, and this chapter contains much that is new and most necessary to be widely known, particularly as to the sequelae that cause invalidism. The measures found imperative for the after-treatment of convalescents are well and adequately described. Stress is rightly laid on the need for evacuating all cases of diarrhoea to field ambulances at once, as well as on the precautions to be taken with "suspected" dysentery. The dangers of waiting for bacteriological confirmation of the diagnosis are not exaggerated.

The story of cholera is well told. If the figures given are exhaustive it would seem that 4,436 cases of cholera occurred in the Mesopotamian Force, as against 3,117 of the enteric group. The case mortality was appalling; it amounted to over 40 per cent. The protection afforded by inoculation with cholera vaccine is unfortunately short-lasting, and inoculated persons who contract cholera show nearly as high a mortality as the noninoculated. The control of the epidemic must have been due quite as much to sanitary precautions as to inoculation. A high proportion of cases thought to be severe diarrhoea only were found to harbour cholera vibrios. Presumably, although this is not stated, the early segregation of cases of diarrhoea was insisted upon, and with somewhat the same degree of success as attended this measure when applied to dysentery. Typhus, as we remarked in our first notice, caused little wastage in the British army.

The research conducted into the etiology and transmission of cerebro-spinal fever is perhaps the most successful and extended medical investigation of the war. For this the navy especially deserves our thanks and congratulation. The conditions were perhaps simpler, seeing that the bulk of cases occurred in England, where access to the best laboratories in the country was available. Still the fact remains that our knowledge of this disease was advanced during and by the war more than that of any other disease. To Glover belongs the credit of making one of those great observations that are magnificently simple: "The space between beds determines the 'carrier' rate; it is carriers, not cases, that spread the disease. Dépôts with beds too close together will have epidemics of cerebro-spinal fever; if the beds are far enough apart the disease will cease to occur." We learnt, moreover, during the war the immense curative value of antimeuingococcal serum administered intraspinally and persistently.

Influenza yields a chapter that is a record of a visitation of the angel of death which, had it come upon the world in peace time, would have overwhelmed us all with consternation. As an incident in the world war it merely added to its horrors. Here again the record is of research patiently and hopefully carried out under stupendous difficulties, to end only in disappointment. At the end we seemed to have added only one fact to our knowledge of the etiology—namely, that the disease was caused by a filter-passing virus. No curative remedy was discovered, no preventive measures proved successful. The pandemic appeared to cease by killing the most susceptible individuals and by immunizing the more resistant after they had survived one or more attacks. Scarcely anyone escaped entirely. The bare recital of the numbers affected fails utterly to give a picture of the state of our hospitals in France during the height of the epidemic. It may be as well that there was no Defoe amongst us to hand down to posterity the dreadfulness of those scenes of mud, darkness, and misery.

The chapters in which malaria is described are patterns of military medical history. The account given of the geography of the disease, the natural history of the mosquito, and the effects of malaria in the several theatres of war constitute a veritable masterpiece whether regarded from the standpoint of medicine, military annals, or literature. The clinical account of the disease has surely never been surpassed for accuracy or graphic detail; the discussion on treatment in both the acute and chronic stages will stand for many years as the authoritative guide. On page 285 is a short account of the handling of the malaria-infected battalions sent to France as reinforcements. Never were men more sorely needed in the front line, never perhaps did a military commander exhibit greater restraint than on this occasion when medical advice was allowed to prevail. Whole battalions were sent sick rather than individuals, with the result that in two months the ague-stricken men took their place in the hardest fighting.

¹ *The Medical History of the War Based on Official Documents: Diseases of the War*. Vol. I. Edited by Sir A. G. Macpherson, K.C.M.G., with the assistance of Sir W. P. Herringham, K.C.M.G., Colonel T. R. Elliott, C.B.E., D.S.O., F.R.S., and Lieut.-Colonel Andrew Balfour, C.B. (Medium 8vo, 1p. viii + 550; 6 coloured plates and other illustrations. £1 1s. net; post free £1 2s.)

with less than average wastage from sickness of all kinds. Here is a lesson not to be overlooked by combatant officers, to whom indeed the credit of having made the experiment possible is chiefly due. Trypanosomiasis and the relapsing fevers did not loom large in their influence on military operations, but our world-wide empire may some day find the facts recorded of great importance.

Phlebotomus or sand-fly fever proved especially troublesome in the Near East and in Mesopotamia. The treatment was preventive, and required ruthless efficiency in fly destruction.

In a short article a very good account is given of trench fever. This was a most mysterious disease. Evidently it was spread by lice, but how is a question still unanswered. American opinion believes that it can be transferred from man to man by the simple bite of the louse; British observers think that the entrance of the faeces of the infected insect into a bite, scratch, or abrasion is essential. This difference of opinion detracts in no way from the credit attaching to the happy observation of McNee, Renshaw, and Brunt that the virus was blood-borne. The invalidism caused by trench fever was probably higher than that caused by any other disease of the war. It is singular that although relapses appear to be frequent and the symptoms are protracted the disease was not introduced into England either during or after the war. Yet the infected men and the lice certainly arrived in this country. We are not convinced that the explanation offered for this phenomenon is correct. There seemed to be districts even in France where trench fever did not flourish, despite the lice. Spirochaetal jaundice was an interesting disease seen occasionally; it attracted attention because of the dramatic course run by fatal cases and because of the comparative novelty of spirochaetal infections in general. As a war disease it counted for little. In the East epidemic and catarrhal forms of jaundice were fairly common; more than one organism was probably responsible.

Of all the diseases prevalent during the war none, perhaps, were subjected to more thorough scientific investigation than the group known as the food deficiency diseases. Before the war we knew of their existence; it had also been discovered that foodstuffs contained certain accessory nutritional factors or vitamins. During the war the necessities of whole nations trying to live on the scantiest food supplies stimulated even governments to study food problems scientifically. Disease among the troops and famine among the civilians provided only too much experimental material for observation.

Thus it came about that our knowledge of four diseases—scurvy, beri-beri, famine dropsy, and pellagra—was advanced during the war beyond all expectation. Lind's book on scurvy was published in 1754; the next book in English was written by Hess in 1919, and practically the whole of the new work it contained had been done during the war. It was not until the war that Miss Henderson Smith discovered that limo juice was relatively useless. Ration limo juice failed to cure scurvy in Mesopotamia. The facts will bear retelling at length. "Limo juice" was introduced as a ration for the British navy in 1804, but down to 1875 lemon juice was in fact issued under this name. Since 1875 the "limo juice" supplied has been true limo juice from the West Indies, and would therefore be much inferior in antiscorbutic value to lemon juice. On this point control experiments were made in Northern Russia in 1919 by Captain A. J. Stevenson, who found that the addition of four ounces of lemon juice freshly prepared from fresh lemons gave markedly beneficial results. The Report of the Royal Society War (Food) Committee is clear and definite: "West Indian limo juice, as ordinarily prepared, is useless for the prevention of scurvy. Fresh limes have an antiscorbutic action, but their efficiency is only one-fourth that of lemons. . . . Nares's expedition of 1875, notorious for the serious outbreaks of scurvy encountered, was the first to be provisioned with 'limo juice' prepared from West Indian limes." If as seems to be the case, judging from an answer to a question in Parliament, the navy is now using West Indian lime juice again, scurvy will reappear should the remainder of the ration at any time fail in adequate antiscorbutic vitamin, unless, of course, lime juice is supplied merely as a pleasant summer drink and some special antiscorbutic ration is being issued. The great outbreak of scurvy among Indian troops in Mesopotamia produced a state of affairs that can only be likened to what happened during the Walcheren expedition. The temperate tone of the article is surprising considering the circumstances. The writer is to be commended for concentrating attention on the admirable way in which remedies were found rather than on the causes which

gave rise to the disease. The discovery of the antiscorbutic properties of germinated lentils and peas together with that of the value of "marmite" as a preventive of beri-beri were two remarkable achievements. In these two preparations a portable ration has been obtained which should safeguard our troops in any future campaigns. Any doubt, too, that beri-beri is a food-deficiency disease has now been dispelled by the researches and experiences of the war.

Famine dropsy was a disease of civilian populations and prisoners of war rather than of armies. Nevertheless it was so purely a war effect that it is properly included in this history. The most interesting part of this chapter is the bringing to light of the excellent but long-forgotten work of Dr. Cornish in the Madras famine of 1877-78. Seeing that the reward of his services at the time was the removal of his name by the Calcutta Government from the list of honourable recommendations, the tardy justice done to his memory is welcome. Pellagra is a disease the precise etiology of which presents a problem as yet unsolved. Wilson's observations, however, on the biological value of protein are of the utmost importance to the scientific study of dietetics. His conclusion cannot be gainsaid: "Lack of sufficient biological value of protein stands in etiological relation to pellagra, certainly as an exciting factor and possibly as the determining factor." The report of the Committee of Enquiry regarding the prevalence of pellagra among Turkish prisoners of war will stand for years to come as a record of one of the best and most scientific inquiries ever accomplished by a nation at war.

The frequent occurrence of nephritis among the troops in France and Flanders gave rise to the impression that there might be some peculiar form of nephritis to which troops in a war area, and especially those serving in the trenches, were liable. The survey of the malady and of the investigations into its nature make it probable that it is not a distinct and separate form of nephritis. The unusual frequency of dyspnoea, dropsy, and uraemia in soldiers is perhaps to be explained on the ground that the exertions demanded of soldiers go to the utmost limit their strength permits. The prognosis from the point of view of ultimate invalidism and pension claims is a matter of vital importance; it is to be regretted that so little information has been collected on this aspect of nephritis attributable to war service.

Cardiovascular disorders formed a large group of medical casualties and since the war have presented serious problems of special difficulty. It seems possible that the importance of minor degrees of organic valvular disease was underestimated whilst the war was in progress. This chapter alludes to the number of men seen by pension boards whose subsequent malady has assumed the form of progressive infective endocarditis. On this point the writer might have spoken with greater emphasis and certainty. The evidence is weighty and still accumulating. Medical opinion should be expressed far more firmly on this matter, as it is one of the principal points on which the recommendations of medical boards are sometimes not followed by the Ministry of Pensions. The discussion of functional disorders of the heart is one of the best that has been written on a most troublesome problem. The short description of treatment and prognosis contains in a readable epitome a great deal of information gathered by many painstaking observers and patient commandants of convalescent camps. In conclusion, it may be said that if the other volumes of the *Medical History of the War* are as good as this one medicine as a whole will have gained much advantage from its publication.

COMPARATIVE ANATOMY.

A Laboratory Manual for Comparative Vertebrate Anatomy,² by Professor HYMAN of Chicago, constitutes a successful effort to provide a practical book for the study of zoology arranged on the comparative plan. In the preface the author indicates the advantages of the comparative over the type plan, and the manual fully justifies the claim that by the former method a student acquires an understanding of vertebrate and human structure which he is unable to attain by the latter. The book may be highly recommended to medical students, since it gives such a clear conception of the "history of the human body," and is not overburdened with details which obscure fundamental principles.

² *A Laboratory Manual*
Hyman. Chicago: The
16mo, pp. xv+380: 6s 6d
Comparative Anatomy. By L. H.
1922. (Double 10s.)

The manual is essentially a guide to practical work, but a necessary amount of explanatory matter is included, and an important feature is the insertion throughout of references to standard textbooks which may be consulted most profitably for the acquisition of further and more detailed knowledge upon particular points. A study of the book makes it manifest at once that the author is not only possessed of wide knowledge, but is also a teacher who has found the best method of presenting his subject. The descriptions of the structure of the various animals are given in a clear and simple style, and care has been taken to define as accurately as possible the meaning of all technical terms. The animals described have been selected with great discretion, and with the chief object of presenting as directly as possible the story of the evolution of the various systems. A helpful feature is the insertion at the end of each chapter of a good summary, which briefly correlates the most important facts before the reader passes on to new ground. For a first edition the manual is remarkably free from mistakes, although on page 311 there is a very obvious one, since we are informed that the abducens nerve "penetrates the eyeball at the point of origin of the external rectus muscle."

The manual is not so liberally illustrated as most of its kind; there are only sixty-nine illustrations, but these are simple, clear, and sufficient, since the instructions for dissection are so arranged that any student ought to be able to display and examine all the features referred to in the text and make his own diagrams direct from his dissections. The book concludes with a good index and two appendices, the first dealing with the pronunciation and derivation of technical words, and the second with methods of preparation of materials.

TESTICULAR GRAFTS.

We have received from Dr. SERGE VORONOFF, director of the laboratory of experimental surgery of the Collège de France, Paris, a copy of his illustrated monograph,¹ in French, on the subject of testicular grafts, and also an English translation of a paper on the subject, which he had intended to read to the thirty-first French Congress of Surgery in Paris this month; some objection, however, was, we understand, taken, and the paper was, in fact, not read. Dr. Voronoff afterwards gave a lecture which seems to have attracted a good deal of attention in the general press; it may, therefore, be convenient that we should give an early account of Dr. Voronoff's claims.

Dr. Voronoff reported the results of 120 testicular grafts performed on animals to the twenty-eighth French Congress of Medicine in October, 1919, and since then he has applied to man the method which he had practised on animals. The first experiments were made by grafting the testicle of a lamb upon a female sheep; the apparent result was that the growth of bone of the limbs of the progeny of the sheep was modified, the legs being shortened. In other experiments testicles were grafted into young female goats from a male; the ovaries had previously been removed; the goats remained small, their limbs were shorter, and their horns were thicker than those of normal goats. Numerous testicular grafts were made upon castrated animals and he-goats in order to ascertain if transposed testicles could play their ordinary part in animals deprived of their own testicles, and replace them in their functions as endocrine glands. In one case, which Dr. Voronoff gives in detail, the grafted testicles apparently performed their functions as endocrine glands, dominating the secondary sexual characters of the male animal, his sexual instinct, and his virile capacity. Other similar grafts made upon castrated he-goats and rams gave analogous results in every case in which the graft did not slough or was not too quickly absorbed. Testicular grafts were also made upon two senile rams aged about 10 years, with the result that two months later a change in their bearing was observed, and their broken-down air and dull look gave place, it is stated, to a vivacity of movement and a bellicose disposition. Their vigour increased considerably from month to month, and, isolated in separate pens with female sheep, one became the father of a lamb and the other of two. In one of these rams the grafted testicular fragments were removed at the end of fourteen months, when the condition of the animal declined once more and its vivacity disappeared; a new graft was then made, and—while not so rapidly as on the first occasion—some months later there remained no trace of its senile

condition. Several photographs of these animals are given. This experiment, which was repeated several times upon other old animals, apparently showed that the graft could be renewed and successive rejuvenations obtained.

Dr. Voronoff gives particulars of a number of cases of testicular grafts from cynocephalus monkeys which were made upon man between June, 1920, and February, 1921.

In the first two cases the patients had suffered from tuberculosis of the testicles, which had consequently been removed; the grafts provoked latent suppuration and proved unsuccessful, although in the second case the man's beard had commenced to grow again.

The third case was that of a man aged 59, who had had gonorrhoea as a youth, and complained of loss of memory, decreased capacity for intellectual work, and physical depression. Testicular grafting resulted in much improvement in his general health, and he is stated now to experience a physical well-being long unknown to him. He has recovered his memory and his mental vigour has been renewed.

The fourth case was that of a celebrated man of letters, aged 61, who, before the graft, was of a senile type, with wrinkled face and dull eyes; his mental activity had become slow and his memory had failed. Two years after a testicular graft had been performed he recovered a virility he had lost for ten years, was well set up, and gave an impression of youth and vigour; he took long walks and could again work for long hours without fatigue.

In the fifth case the subject was an American, aged 33, who was neurasthenic, melancholic, and dyspeptic. A year after the testicular grafting he enjoyed perfect health and virility, and although Dr. Voronoff suggested to him that a romantic love affair which had ensued might have played a more important part than the graft the patient repudiated the suggestion.

The sixth case was that of a South American of 66, who suffered from senility and depression, aggravated by gastric ulcer; after a testicular graft had been performed he experienced physical well-being and a new sexual vigour.

An Englishman of 74, whom Dr. Voronoff had arranged to exhibit to the Congress, was the seventh patient. Two years before the graft this patient seemed to be an old man, inert, obese, haggard, walking painfully with the aid of a stick. Eight months after the graft was performed he appeared before Dr. Voronoff with half his embonpoint gone, his aspect jovial, and his movements active. His condition was stated to-day to be still that of a man who had recovered twenty to twenty-five years of his lost youth. Several photographs of this patient, in vigorous attitudes, are given in the monograph.

Dr. Voronoff does not admit the possibility of grafting the testicles of animals other than monkeys upon man, and human grafts are apparently impossible to procure. From February, 1921, to March, 1922, he was unable to obtain any large monkeys, and no further grafts were made until March, 1922; the results of these later cases were too recent to afford proof of benefit.

Dr. Voronoff thinks that he has established the efficacy of testicular grafting in senile conditions due to the insufficiency of the internal testicular secretion, and not due to affections causing deterioration of essential organs of the body. He does not attribute senility only to the diminution or disappearance of the internal secretion of the genital glands, but he thinks that human force and energy are bound up with the activity of the sexual glands. It is logical, therefore, in Dr. Voronoff's view, to suppose that by supplying the testicular hormone to the body at the moment when its own glands no longer elaborate it the body is really rejuvenated. Whether the testicular graft would be of utility under other conditions, as an organic stimulant of the enfeebled functions of other endocrine glands or of tissues upon which the testicular hormone had a more direct action, are, he states, questions to be decided by further experiment. Placed under the skin or under the muscles, the grafts, even under the most favourable conditions, only survive in part: the centre necroses; the cortex usually survives but is reabsorbed in a few months. Placed, however, in such a position as the peritoneal cavity or the tunica vaginalis, where exudation can be made rapidly, the graft may survive for several years. A graft of the entire testicle may be made, but it must be of small volume and young; for the most part the grafting of fragments is preferable. Dr. Voronoff advises that the testicle should be divided into two, four, six, or eight portions according to its size, the tunica albuginea scarified lightly, and the fragments attached by a catgut suture above and below in such a way that the glandular face is in contact with the tunica; the fragments should not touch each other, but should be everywhere in direct contact with the tissues of their new host. Dr. Voronoff now supports the view of Professor Retterer, who affirms that the epithelial cells are the agents of the cellular secretion, both internal and external, and that the seminal cell is at once exocrine and endocrine. When in testicular grafts these cells are deprived of the excretory canal they cease to elaborate the spermatozoa, and act only in the endocrine sense; to the interstitial cells a nutritive function is attributed.

¹ *Greffes Testiculaires*. By Dr. S. Voronoff. Paris: G. Doin. 1922. (Roy. 8vo, pp. 83; 19 illustrations.)

CONTROL OF CONCEPTION.

LADY BARRETT has written an essay of less than fifty pages on *Conception Control*,⁴ in response to requests for some statement regarding the individual and national aspects of this widespread practice. She writes as a medical practitioner and a specialist in gynaecology; but her object is not so much to give medical advice as to place before the lay reader her considered opinion upon the social and hygienic issues underlying the problem. Her view is that medical advice on this matter is best given to the individual by his or her medical adviser, and must depend on the circumstances; whether control of conception shall be practised when husband and wife are healthy is, she holds, an ethical question for the individual pair, and not a medical question to be decided for the public at large. She is concerned at the careless advocacy of an indiscriminate use of contraceptives, believing that if this goes on various harmful effects will soon show themselves: "In the whole discussion of this subject it is important to keep in mind that the physical is only one aspect of the sex relation."

So far as we understand her, Lady Barrett takes a broad view of present-day difficulties. For ordinary couples she seems to favour some measure of voluntary self-control, not merely for its spiritual and aesthetic advantages but as a practical means of limiting the size of a family, while living a natural married life. The method she finds least harmful for controlling conception is "the avoidance of those parts of the monthly cycle in which conception most commonly takes place" (p. 35), but she does not add that the efficacy of continuing intercourse to one week in the month has been challenged. She detects serious fallacies in the arguments of those who advocate the widespread teaching of mechanical and chemical methods of preventing conception. In particular she deprecates the current doctrine that child-bearing may safely be postponed by young married women, and that children will come in abundance to all unless actively prevented—"Advice which may be quite necessary in cases of ill health or special conditions may be fundamentally wrong to give broadcast to all." It is her experience that, as a result of the ideas conveyed to the minds of young people by books and speeches, many of them though anxious to have children "start married life with sordid and unnatural preparations for a natural act" in accordance with the vogue of the moment. Her own belief is that, apart from those who for physical reasons or because of hereditary taint should not bear children, married love ought to express itself at once in the usual way without the use of artificial contraceptives. Notwithstanding the efforts now being made in "birth control clinics" for working-class women, she is convinced that this propaganda will have a disastrous effect on the differential birth rate of the community, "for the birth rate amongst the least intelligent, least efficient, and the mentally deficient, will be unaffected . . . the diminishing fertility of the more capable classes is a national peril."

Lady Barrett's position seems quite clear: wherever child-bearing is fraught with danger conception must be prevented, by means chosen to suit each special case; but public instruction in the use of contraceptive devices is generally misapplied and is therefore detrimental both to health and morals. She does not agree with the "spacing" of families by the regular use of artificial checks; if the family is to be limited to three or four it is better for everyone concerned that the children should all be in the nursery together, and later all at school. Her objection on medical and aesthetic grounds to most of the usual contraceptives is stated very plainly in Chapter III; though here and elsewhere throughout the book her language is commendably restrained, and all personalities are eschewed.

What solution does Lady Barrett suggest for the large problem presented by the falling birth rate among the educated and prosperous, and the excessive childbearing among the poorer and less efficient classes? She accepts the view that fertility, broadly speaking, varies inversely as the nervous energy or general vitality; and her remedy is to raise the standard of living among working-class mothers and to advise a simpler life for the more richly endowed.

We have tried to give an uncoloured account of the purpose and manner of this able and thought-provoking tract, which should be read by all medical men and women.

⁴ *Conception Control and its Effects on the Individual and the Nation*. By Lady Barrett, C.B.E., M.D., M.S., B.Sc., Consulting Obstetric and Gynaecological Surgeon to the Royal Free Hospital, President of the Federal Council of Medical Women. With a foreword by the Archbishop of Canterbury. London: John Murray. 1922. (Cr. 8vo. pp. 48. 2s. net.)

THE DISCOVERY OF THE CIRCULATION.

THE first volume of the series of *Classics of Scientific Method*, which is designed for the instruction of those without any previous knowledge of the subject, is on *The Discovery of the Circulation of the Blood*,⁵ and has wisely been entrusted to Dr. CHARLES SINGER. The description of the circulation is therefore rightly elementary, but most medical men will find that they can learn a good deal from the clear historical survey of the records and workers by whom the full discovery of the circulation was achieved; the biographical details add to the interest of the well-told story. After a sketch of the knowledge of the vascular system in antiquity, in which reference is made to Hippocrates, Aristotle, and more fully to the views of Galen, Dr. Singer passes on to the period of the Renaissance and to Leonardo da Vinci (1452-1518), who, he holds, was the first to question the authority of Galen and to give a more correct description of the anatomy of the heart; he intended to publish a textbook of anatomy and physiology, but did not live to do so, and accordingly the epoch-making appearance of the first great book on anatomy and physiology since Galen's time was the *Fabrica* of Vesalius in 1543, in which the statements of Aristotle and Galen were tested by the author's own observations; doubt was thus cast on the received belief that the blood passed from the right to the left ventricle through the inter-ventricular septum of the heart. A little later Michael Servetus, a contemporary of Vesalius and the martyr victim of Calvin, made known the circulation through the lungs in a book which was burnt with its author at the stake in 1553. Of Vesalius's successors, Fabricius of Aquapendente was professor for fifty-four years at Padua, and thus was the instructor of William Harvey, who in his Lumleian lectures at the Royal College of Physicians of London set forth his great discovery in 1616, and gave it a wider public by publishing the *De Motu Cordis* in seventy-two small pages at Frankfurt in 1628. The discovery of the capillaries and red blood corpuscles is illustrated by reproductions of plates from Malpighi and Anthony van Leeuwenhoek's works. This is a book full of information presented in a pleasant style, with good illustrations, and at a remarkably cheap price.

MERCHANT SEAMEN.

In a review published under this title last week (p. 692) reference was made to a paper on the preservation of the health of seamen on board ship, read by Dr. Arnold Chaplin to the Section of State Medicine of the Royal Society of Medicine. In the endeavour to be brief a phrase was used which did not adequately express Dr. Chaplin's opinion, and may have conveyed the impression that in his view all ship-owners were negligent and careless concerning hygiene. This is far from the case; otherwise the big lines would not have appointed competent medical advisers and able medical officers. We may perhaps best put the matter right by quoting the paragraph from Dr. Chaplin's paper:

"A ship, as we understand it to-day, is the result of innumerable compromises, and this fact can hardly be insisted upon too strongly. The passenger would prefer the ship to be all luxury and comfort, the sailor easy to handle, and the owner economical to work. So also where health is concerned; the hygienic enthusiast would build his ship much as he would a sanatorium or a hospital, and he might regard the owner as unreasonable if he pointed out that his ship was designed, not to carry sick people, but passengers and cargo. In every department of a ship, whether it be the engine room, the crew quarters, the cargo space, the passenger quarters, or the medical arrangements, the final result has been obtained by means of compromise. This means that no department on board ship can approach the ideal without encroaching upon some other department. I would therefore beg of you to dismiss from your minds the idea that the principles of hygiene on board a ship can be satisfied in the same way as on shore, where space has few limitations. I would also ask you to remember that the main object of a ship is to carry on our commerce, and that nothing should be done to interfere with that object so long as the reasonable laws of health are obeyed."

Dr. Arnold Chaplin's paper, "Certain measures for preserving the health of seamen on board ship," was published in full in the *Proceedings of the Royal Society of Medicine*, 1921, vol. xiv (Section of Epidemiology and State Medicine), pp. 23-37.

⁵ *The Discovery of the Circulation of the Blood*. By Charles Singer, M.D., D.Litt., F.R.C.P. *Classics of Scientific Method*, edited by E. R. Thomas, M.A., M.Sc. London: G. Bell and Sons, Ltd. 1922. (Cr. 8vo. pp. x + 80; 8 plates. 1s. 6d.)

British Medical Journal.

SATURDAY, OCTOBER 21st, 1922.

THE WHOLE ART OF MIDWIFERY.

THE sketch of the development of the Edinburgh school of obstetrics and gynaecology with which Professor Watson began his inaugural lecture, published at page 712, is full not only of historical interest but of instruction useful to us to-day.

To Edinburgh belongs the honour of being the first teaching centre to have a professor of midwifery; nearly two centuries have elapsed since the town council appointed Joseph Gibson, a surgeon, "to be professor of midwifery in this city." His duty was to teach women midwives, and he and his successors discharged it so well that by the beginning of the nineteenth century it could be said that there was "scarcely a parish of Scotland the midwife of which has not been regularly taught." Though the town council of Edinburgh was the patron of the university, the relations of the one to the other were not always smooth. The council was proud of the university, but occasions for strife arose, and the university did not at once recognize the new chair. A century was indeed to pass before it made midwifery a compulsory subject in the medical curriculum. Ten years later, in 1840, the university was fortunate enough to secure for the chair of midwifery a man of genius, and James Young Simpson's strong personality, originality of mind, and inspiring teaching firmly established obstetrics and gynaecology as an essential part of the medical curriculum. He and his successor, Alexander Russell Simpson—and between them they cover sixty-five years of the Edinburgh school—were both obstetricians and gynaecologists, and this brings us to the kernel of Professor Watson's address. The two subjects, especially when we regard prevention of disease, are one, and that their recent divorce at many schools in America and Europe was a retrograde step is the opinion in Edinburgh and Toronto, two of the wisest and most progressive medical faculties among English-speaking peoples. It is a curious example of the swinging of the pendulum and of the solidarity of the profession in Great Britain and the great Dominion that when in 1912 Toronto was looking for a professor to unite the two chairs it found the man it wanted in Edinburgh, where until a few years earlier the two had been one, and that when Edinburgh determined to abandon the experiment of division it had begun seventeen years ago it brought back its old alumnus to occupy the single chair it had restored. In Edinburgh the evils of division were hidden because Sir Halliday Croom, appointed to the restricted chair of obstetrics, was not less eminent in gynaecology, and Dr. Freeland Barbour, appointed lecturer in gynaecology, had won his spurs in obstetrics.

When we examine the reasons Professor Watson gives for his very decided opinion against separation we find the chief to be bound up with the pioneering work of another ornament of the Edinburgh school, Dr. J. W. Ballantyne. For a long time he got very little encouragement, but he was given courage to persevere by the consciousness that he was building on a sound basis of pathological observation. It is a little over thirty years since he published his *Introduction*

to the Diseases of Infancy, a book many laid down with the observation that the author had never got to his subject, for much of it was about the anatomy of the newborn infant, a little of it about pathology, and very little about clinical appearances. This criticism was mistaken, as experience, reflection, and the persistent and persuasive advocacy of the author have proved; so true is this that, like some other pioneer Ballantyne is at risk of his early work being forgotten owing to his very success in making his doctrine the common possession not only of the profession but of the public.

We may leave this part of the field, where the battle has been won, for another, where, though the final result is not in doubt, it has not yet been attained. Preventive midwifery is not quite a new subject, but its rational study on scientific lines is. Professor Watson gives a definition of preventive midwifery: it is ante-natal care during pregnancy, a minimum of interference during labour, the most rigid attention to asepsis, and the earliest possible carrying out of surgical intervention when it is required after the puerperium. Here again Ballantyne was a pioneer, and even those who have followed the subject most closely will be surprised by the reminder that it is over twenty years since he made his first plea for a pre-maternity hospital.¹ Professor Watson, who speaks from nearly ten years' experience in the obstetrical department of the Toronto General Hospital, says that a pre-maternity or ante-natal department is the most essential part of a maternity hospital.

Professor Watson only accepts the midwife with reluctance; her training, he says, interferes with that of the medical student, and her want of general medical education limits her usefulness in the all-important work of ante-natal care. The second objection is well grounded and might perhaps be extended to post-natal care also. The promoters of the Midwives Act were mainly influenced by the fact that, in England at least, attendance in a large proportion of cases was given by women who while they called themselves midwives, had not learned the essential importance of cleanliness, had not been taught to recognize conditions arising during labour which made skilled medical assistance necessary, and were unable to appreciate when surgical aid was afterwards needed. The Midwives Act has not done all its promoters hoped; there are still many untrained women and some men acting as midwives, and some of the untrained women certified when the Act came into force are still in practice. But on the whole it has done good and any scheme for the improvement of the actual practice of midwifery must take the certified midwife into account, though no effort should be spared to increase her sense of responsibility, and in this we would include full realization of her own limitations.

This is not to say that the medical profession is to lose control of midwifery. If the ideal put before us is to be realized, and when it has been realized, there will be much highly responsible work for the general practitioner to do. The first task is to convince women of the value of consulting their doctor at an early stage and at intervals afterwards to make sure that all is right. They already do so to a considerable extent, and there will probably be no great difficulty in inducing them to make it an established custom. Professor Watson says he has found none. There may be a little more difficulty persuading them to come again a month after delivery. The troublous time is over and they have new interest but the request is so rational that it will appeal to their reasoning faculty in women, and, as we all know, that can be very rational on occasion. All this implies the establishment and maintenance of a high standard in the

¹ It was published in our columns on April 6th, 1901 (p. 813).

teaching of obstetrics and gynaecology to medical students, a subject on which Professor Watson touched rather lightly at the end of his thoughtful and stimulating address.

Thus we come back to what we have ventured to call its kernel—the essential unity of obstetrics and gynaecology, and the imperative need to teach them as one subject. Thus also we justify the title of this article, for the whole art of midwifery does not consist in procuring the safe delivery of a living child, but in ensuring also that the mother shall not experience any preventable injury or later suffer from any remediable damage due to her having passed through the physiological process of childbirth.

MEDICINE AND THE RENASCENCE.

THE annual commemoration of its benefactors on St. Luke's Day, October 18th, is an occasion for the Royal College of Physicians of London to unhand. Harvey, when he founded the annual oration which bears his name, clearly stated his aims. His main objects were that the Fellows should be reminded of their chief duties as physicians—to be diligent "to search and study out the secrets of Nature by way of experiment; and also for the honour of the profession to continue in mutual love and affection." Harvey was not only the first of physiologists, but for the best years of his life actively engaged in practice—he was physician to St. Bartholomew's Hospital as well as to the King. He was therefore well qualified to admonish physicians, and his injunctions were so well and widely conceived that they succinctly express the aims of the British Medical Association, which seeks to apply them to the whole profession. The appeal of the orator extends far beyond the audience he actually addresses; Harvey desired the oration to be public, and the occasion affords the College an opportunity of inviting men of light and leading in other callings to hear the oration, and to share in the less formal celebration at the banquet which Harvey directed should afterwards be held.

Over two hundred Harveian Orations have been delivered, and if the injunctions of the founder had been less widely drawn, or if they had not been interpreted rather in the spirit than the letter by succeeding orators, the profession might have been treated to as many examples of formalism. But though every orator has felt it becoming to bring what he has had to say into some relation with Harvey, he was so many-sided a man, so endowed with intellectual courage and independence, so possessed with divine curiosity to search and study out the secrets of Nature, and so well versed in the learning of his time, that to find a new point of view from which to regard his work or illustrate it has not been a task as difficult as might have been anticipated.

The chief aim of the orator this year was, as may be seen from the full text of his oration published at page 707, to draw a picture of the kind of intellectual world into which Harvey was born. Just recently there has been a great pothar among the log-rollers who write columns of "literary gossip" about the discovery of some of their number that Shakespeare was the child of his age, influenced by the currents of thought then prevailing and by the events of the day. For biologists the question is, not to affirm the influence of environment, but to determine where to trace its limits. Dr. Arnold Chaplin is too much of a man of science to consider it worth while to discuss this aspect of his subject, and too good a humanist not to assign great importance to the revival of learning in Western Europe which had begun about a century before Harvey's birth. The orator thus

became involved in an attempt to explain the renaissance. For him it dates fairly definitely from 1453, when the Ottoman captured Constantinople. He does not, however, altogether forget that the West had earlier been in contact with the Greek Empire. There had been the Crusades; no doubt the motives of the men who were swept off their feet by that remarkable movement were mixed—in part they were religious; and a reaction against Mohammedan propaganda and conquest, in part they were due to a love of adventure, but in part also to a new spirit of inquiry and curiosity. The same age saw the birth of scholasticism, founded on the study of the masters of Greek metaphysics, of whom Aristotle, the chief, enjoyed a kind of mystical authority, so that the conclusions even of his commentators could not safely be questioned. The more settled conditions of government which Western Europe owed to the administrative genius of the Normans not only made the Crusades possible, but favoured the growth of learning within the cloister, and also, though to a very limited extent, outside it. There was already a certain stirring of men's minds in Western Europe; Dr. Chaplin probably comes very near the secret when he tells how the Church became aware that its power needed support to be obtained only from an appeal to the intellect. As evidences of this we may note in passing that the University of Bologna came into existence in the middle of the eleventh century and had acquired a European reputation as a school of jurisprudence before its end, and that the medical school of Salerno dates from the middle of the twelfth century. Western Europe had indeed been prepared to benefit by the opportunity given to it when Greek scholars fled from conquered Constantinople to find a refuge in Italy, and when the Ottoman readily sold original Greek manuscripts to the princes and merchants of that country. Hitherto the West had seen the ideas of the men of the great age in Greece through the dark glass of Latin translations or paraphrases of Arabian versions, and the same was true of the later Galen, whose writings, in spite of his own and his commentators' errors, had attained an authority as of holy writ.

Dr. Chaplin has done good service by tracing out what followed. The first stage was to establish the authentic Greek texts, to understand them truly, and to learn the lessons they had to teach. This was the task of the humanists, the task in medicine of the scholar-physician, of whom Linacre was one of the earliest—the earliest in England—and Caius one of the greatest. What was to be learnt from the great Greeks, however, was method rather than fact. Men began to perceive that it was unsafe to rely on written authority, and necessary to search and study out the secrets of Nature by direct observation and experiment. There was a change of spirit, and the first-fruits of the new spirit was the foundation of scientific anatomy by Vesalius; his teaching attracted inquiring minds from all over Europe, as Dr. Herbert Spencer more fully showed in the Harveian Oration of last year. Vesalius's great book was published in 1543, and three-quarters of a century later Harvey laid the sure foundation of the scientific study of function by his work on the heart. His little book swept away an enormous superstructure piled up on a basis of inaccurate observation and buttressed by fanciful conjecture. The impetus Harvey gave to physiological inquiry was, as the orator truly said, marvellous, and it is not yet exhausted. Rather it seems to gather strength; the growth of physiology and the immense influence it is exerting on the practice of medicine would have been a source of the deepest satisfaction to those great humanist scholar-physicians of whom Dr. Chaplin draws so pleasing a picture.

A CASUALTY DEPARTMENT FORTY-FIVE YEARS AGO.

THE Poet Laureate celebrates his 78th birthday on Monday next, and it is forty years since he retired from medical practice and gave up the posts of assistant physician at Great Ormond Street and physician to the Great Northern Hospital. His strictly medical writings have been few; the only one we can trace—if we except his recent helpful disquisition on the language of anatomy to which we referred at length on August 12th (p. 276)—is a note contributed many years ago on a case of severe rheumatic fever treated with splints. But in 1878 Dr. Robert Bridges wrote a remarkable paper entitled "An account of the casualty department,"¹ describing the medical work of the old surgery at St. Bartholomew's, where he acted as "filtrator" of out-patients from 9 o'clock till past noon, spending (as he found) on an average a minute and a quarter over each case. Some 158,000 patients were relieved at St. Bartholomew's Hospital in the year 1877. Pondering over this vast number he asked himself several questions, such as, "Where in the world do all these patients come from? What is the matter with them? Have they anything the matter with them? What becomes of them afterwards? Do they ever go there again? How is it possible to attend to them when they do go? How are they counted, sorted, recognized, prescribed for, dispensed for? What quantity and what sort of medicine do they consume? What does it all cost? Who pays for it, and what is the use of it?" The main question, however, to which he applied himself, was: "How can they be attended to?" and his answer gives a vivid picture of the machinery of the old casualty department and its work forty-five years ago. Those who performed the feat each morning of clearing the hall of medical casualty patients consisted of Dr. Bridges and two other casualty physicians, and the junior assistant physician, who each attended four mornings a week. Among the problems of a casualty physician was "to weigh the inconvenience of overcrowding the hospital dispensary against the lesser, or at least less visible, inconvenience of treating a number of different complaints with the same medicine; but what stands most in his way is no doubt his want of time. . . . And yet filter he must, and filter quickly too, and be prepared to hear his quick filtrate shamefully ill spoken of in the wards and in the out-patient rooms. . . . He will decide at once that what he has to do is the best that can be done for every individual case under the circumstances, and he will make the best of a bad business, and take it patiently." Feeling thus the responsibility and difficulty of the task, Dr. Bridges made a system of hieroglyphic notes for checking off each case as he dismissed it; these records formed the statistical basis of his paper. At that time he saw 7,735 patients in three months, or some 30,000 patients in the year, and of these more than two-thirds were new cases. In the three months nearly 2,000 of his patients took quassia and iron, affectionately known as "Queen Anne" mixture—"a medicine which I selected to give as frequently as possible in consideration of its strong taste, cheapness, and innocuous properties." Allowing for the exiguous sum paid to the casualty physician, it appeared that the total cost of his "Queen Anne" patients was well under twopence a head. Dr. Bridges found that in the year he took book-notes of only 70 cases, and reflected on how much rich material for study was daily thrown away. The congested casualty department in his time supplied less than a quarter of the cases in the wards, and he came to the conclusion that the serious cases bore no relation to the trifling ones, and that the former would come in just as great numbers were the latter discouraged. While agreeing that the mistakes were very rare and the treatment fairly satisfactory, he maintained that the system was intolerable and must be reformed. How far reform has gone in forty-five years might be a congenial subject for inquiry by one of our younger medical poets. Great changes were made for the better when the new casualty and out-patient department of St. Bartholomew's was opened in 1907.

¹ *St. Bartholomew's Hospital Reports*, vol. xiv, 1878, p. 167.

BRISTOL MEDICAL SCHOOL.

WHEN Bristol University College was founded in 1877 some of the lecturers in the Medical School—among whom Dr. Shingleton Smith may be specially mentioned—were anxious to see it incorporated completely with the College. This was not found feasible, but the School was affiliated with the College, and after a few years medical students in the preliminary subjects, up to and including anatomy and physiology, received their instruction in University College. This plan was continued when the University was founded in 1909, but complete incorporation was still desired, and this has now being accomplished. The clinical portion of the students' curriculum, which heretofore has been a proprietary affair of the honorary staffs of the Royal Infirmary and General Hospital, has been given over to the University, and the students' fees will be paid in to the University exchequer. The only private right the staffs retain is the privilege of introducing pupils to their hospital practice. This right is derived from a stipulation made between the original founders of the Bristol Royal Infirmary and the first surgeons elected to that institution, whereby the surgeons undertook to give gratuitous service on condition that they were allowed to introduce their apprentices to the wards of the Infirmary. The Bristol Medical School was the foster-mother of University College, and out of the College grew the University; the new arrangement by which the Medical School becomes an integral part of the University cannot fail to strengthen both. The surrender of the management of clinical teaching and the disposition of clinical fees is a big step, one effect of which will be to influence the Government grants to the University. Hitherto the Treasury has not taken into reckoning "clinical studies" in medicine as part of the functions of the University. In a recent communication to the University the University Grants Committee stated that it disapproved of "proprietary" medical schools and would make no grants in aid of them. The staffs of the Infirmary and Hospital became convinced that a change was desirable, and by a unanimous decision clinical teaching and clinical fees have been made over to the University of Bristol as from August, 1922. The University in return has arranged a scale of payments to clinical teachers which, although small, will have the advantage of not fluctuating with the number of students, and moreover is designed to remunerate teachers on the basis of work done—a plan which the old system did not ensure. The new arrangement has led to the appointment of three directors of clinical studies, whose chief duties will be to co-ordinate the teaching at the two institutions, and to organize on a coherent and continuous basis the clinical instruction of medical students. The directors appointed are Professor Edgeworth in medicine, Professor Hey Groves in surgery, and Professor Swayne in obstetrics and gynaecology. These newly appointed directors start with the goodwill of all their colleagues, and the scheme appears to have won the approbation of the students.

SACRAMENTAL HEALING AND THE PSYCHOLOGY OF CONVERSION.

AT the Church Congress which was held in Sheffield last week questions of lively medical interest did not figure so largely as at the last congress, when Lord Dawson spoke on birth control; but the subjects of sacramental healing and of the psychology of conversion came in for some discussion. Dr. Chandler, lately Bishop of Bloemfontein, summed up the Church system of therapeutics as consisting of the sacraments or sacramental rites of confession, unction or the laying on of hands, and communion, and in that order. He said that doctors engaged in mental therapeutics had made the significant criticism of sacramental methods of healing, not that such healing was illusory, but that it was superficial, dealing only with outward symptoms, and not penetrating to deep, underlying moral causes. In many, though not all, cases of functional nervous disorder there was an underlying moral cause, a repressed complex resulting from some moral struggle, and he believed that this cause ought to be dealt with, before the

physical symptoms were touched at all, by a skilled confessor. The priest in confession ought to be able to supply, with equal effectiveness and under more rigorous safeguards, the services which the psycho-analyst aimed at rendering. It was claimed for psycho-analytical treatment that it differed from spiritual direction in securing a more complete and radical cure, so that no repetition of the treatment was needed. He believed that this view could hardly be maintained. It might hold good in certain sudden and violent emotional shocks where the instinctive reaction immediately underground and produced a neurosis; in such cases, of which war shock was a typical instance, the reassociation or breaking into consciousness of the repressed complex might be all that was required to re-establish the normal. But in the more usual cases there was necessity for repeated treatment, either in the way of precaution or cure, and this was best done by the sacrament of confession. Afterwards the physical symptoms might well be treated more directly by the further sacramental rite of unction or of the laying on of hands. The reconsecration of the body to the Divine will which was thus effected came as a natural and proper sequel to the absolution previously received. Finally the whole nature of the man, spiritually and bodily, was strengthened and built up by the sacrament of communion, which aimed at preserving body and soul unto everlasting life. Bishop Chandler claimed that in this way the sacraments, uniting body and soul together had their part to play in the cure of functional disorders although their primary aim was the spiritual good of the sufferer. The psychology of conversion was the subject of another discussion opened by Dean Inge, who criticized the view that conversion was always or even usually a sudden event rather more vigorously than some sections of his audience relished. Dr. William Brown, Wilde Reader in Mental Philosophy at Oxford, who followed, argued that conversion was not primarily psychological; it was religious, which meant that it belonged to a realm beyond the reach of psychology. He held that psychology could not explain the distinctive religious experience, and had to do only with the pathological. It could explain deviations, errors, and evil, but it could not explain normal appreciations, truth, or goodness. He believed that it was better for conversion, or the turning away from the naturalistic to the religious, to come gradually, but there were certain temperaments in which the gradual process was impossible. In these cases conversion was frequently preceded by melancholia, which was an outward and visible sign of maladjustment and of unsolved conflicts in the subconsciousness. The fact that the mystical experience came suddenly did not mean that it was a pathological experience, although in the cases of sudden conversions the danger of pathological characters linking themselves on to the normal process was greater. He was in profound disagreement with the psycho-analytical theory which explained religious experience as a regression to an infantile attitude of mind. There were those who said that when a person became converted he regressed to his childhood, and early tendencies, memories, and fantasies assumed for him an objective reality, although they were only a re-edition of his early experience. In Dr. Brown's view this was far too shallow a theory, and, as with so many other aspects of psycho-analytical doctrine, it was put forward without having been tested by people thoroughly trained in psychology and in philosophy.

THE ABORTIVE TREATMENT OF SYPHILIS AND SALVARSAN RESEARCH IN GERMANY.

PROFESSOR KOLLE,¹ on whom the mantle of Ehrlich has fallen, has been engaged for a considerable time in studying the effects of salvarsan on experimental syphilis in rabbits. The two questions he set out to answer were: (1) Is it possible, and if so in what percentage, to sterilize with salvarsan rabbits infected with syphilis? (2) To how late a stage after infection is sterilization feasible? Kolle

agrees with Finger, Landsteiner, Uhlenhuth, and others, that once a rabbit has been infected with the Truff strain of the *Spirochaeta pallida* it is immune for the rest of its life. This immunity to reinfection from without in the form of a typical primary chancre is conditional on its not having been given any antisyphilitic treatment, and on ninety days or more having elapsed since the first infection. Among the many hundred rabbits he has inoculated he has not seen a single exception to this rule, although in a few cases he has observed atypical infiltrations or ulcers, containing spirochaetes, at the site of a second inoculation. Within the first sixty days of the first infection he has been able to induce reinfection in 50 to 60 per cent., and he has achieved this result in a few instances between the sixtieth and ninetieth days. Within 3, 15, 20, 25, 30, 45, 60, 90, and 120 days of the first infection rabbits were given three large doses of salvarsan preparation, and attempts were made 110 to 120 days after the first infection to induce a typical chancre by reinfection. Various salvarsan preparations were used, and neo-silver salvarsan figures most prominently in Professor Kolle's tables. Changes were also rung with mercury in combination with salvarsan, and the development of a typical chancre after reinfection was accepted as evidence of effective sterilization of the tissues after the first infection. It was found that when this sterilization was attempted within the first forty-five days of infection complete recovery occurred in a considerable percentage, whereas after the forty-fifth day this was the exception. In no single instance in which salvarsan was administered after the ninetieth day did a typical chancre develop when an attempt was made to reinfect. There is thus weighty experimental evidence in support of the clinical finding that the success of salvarsan medication depends largely on the interval between infection and treatment being short, but it is, of course, doubtful whether the forty-five day limit in the case of the rabbit can be accepted as the "sterilization limit" for man. Another interesting observation made by Professor Kolle was that the combination of mercury with salvarsan did not add to the number of his successes, and he claims that this is in accord with clinical experience. The dosage of salvarsan recommended by Professor Kolle for man is 0.45 gram of neo-silver salvarsan, 0.3 gram of silver salvarsan, or 0.5 to 0.6 gram of neo-salvarsan, these doses being approximately two-thirds of what he calls the *dosís tolerata*. He also recommends the injection of a precautionary dose of 0.05 gram of salvarsan twenty-four hours before the main injection is given, and the addition of a 40 per cent. solution of sugar (glucose) to the salvarsan. It will be seen that Professor Kolle has reverted to his predecessor's scheme for a *sterilisatio magna*, although he does not use this term in his paper, and he recommends not one but three to four large injections. He doubts whether the percentage of biological cures can be appreciably increased by a greater number of injections. Investigations are proceeding in his laboratory in connexion with the therapeutic possibilities of prolonged and intermittent treatment of fully established syphilis with salvarsan alone or in combination with mercury, but they are not sufficiently advanced to allow any conclusions to be drawn from them. With regard to the early abortive treatment of syphilis with large doses of neo-silver salvarsan, however, he is very optimistic.

AN INTERNATIONAL CONFERENCE ON TAR CANCER.

AN international conference of those engaged in the experimental study of cancer opens at Amsterdam on October 23rd, and will continue until October 25th. It has been arranged by the Netherlands Cancer Research Society, and Professor Rotgans, Emeritus Professor of Surgery in the University of Amsterdam, will preside. Papers will be contributed by Professor Fibiger and Dr. Bang of Copenhagen, Drs. Archibald Leitch and J. A. Murray of London, Dr. Declman of Amsterdam, Dr. Bierich of Hamburg, Dr. Deutschlander of Heidelberg, Dr. Lipschütz of Vienna, Professor Bloch of Zurich, and Drs. Peyre, Roussy, and Leroux of Paris. Most

¹ *Deut. med. Woch.*, September 29th, 1922.

of the papers will deal with the various phenomena observed in the production of cancer by tar. Dr. Murray will contribute a paper on the criteria of malignancy in experimental cancer, and Dr. Archibald Leitch will read three communications on the effect of cessation of the irritant on the development of tumours, and on the experimental production of paraffin cancer and arsenic cancer. At the end of the conference Professor Fibiger will deliver an address on recent investigations in cancer.

A GOOD OPENING.

Those who have to look through the annual reports of public institutions are not always rewarded for their pains. But now and then a chronicle of dull but useful events is enlivened by a note of criticism, or pages of statistics are prefaced by a few words indicating an outlook wider than the institution grounds. The effect upon the committee must depend largely on how the thing is done. An introductory note to the last annual report by the Medical Superintendent of the Kent County Mental Hospital at Barning Heath has, we suspect, been appreciated. "During the year [he writes] mental disease and its treatment have been much in the public mind. Psycho-analysis nowadays is freely discussed in popular magazines; the man in the street, not a little bewildered by the jargon of the psycho-analyst, ponders on the properties of the subconscious mind, and tries to recall the detail of his dreams. Monsieur Cené, the philosopher from Nancy, draws crowded audiences to his lectures on auto-suggestion, and the daily papers record the remarkable cures that occur at his séances. There is indeed nothing new under the sun! The interpreters of dreams were ever held in esteem by the ancients. Buddha, Mahomet, the Shrine at Lourdes, the King's Touch, are but a few of the agencies that have effected cures by auto-suggestion. It is not generally recognized that the emotions are more powerful than the intellect, and that the imagination is stronger than the will." Next follow a word or two about *The Experiences of an Asylum Doctor*, and the advantage of ventilating a matter which in the past has been too much "wrept in mystery"; a hint on the need of better opportunities for training the medical and nursing staffs of the great mental hospitals; and a suggestion that greater facilities should be given for treating mental disorder in its earlier stages. Having thus whetted his readers' interest, Dr. Wolsley-Lewis proceeds to the record of a year's work, mindful perhaps of Bacon's advice to negotiators: "A man may not look to sow and reap at once; but must prepare business, and so ripen it by degrees."

THE VITAL STATISTICS OF ONTARIO.

According to the last annual report on the vital statistics for the province of Ontario, Canada, the estimated population in 1920 was 2,895,370. The distribution of the population was as follows: the cities contained 54 per cent., the towns with a population of over 5,000 5.8 per cent., and the rural municipalities, villages, and small towns 40.2 per cent. The birth rate for the whole province was 25, and the death rate 13.9 per 1,000 of the population. The chief cause of death during the year was influenza, which accounted for the deaths of 113.1 persons per 100,000 of the population. This was due to an epidemic during the autumn and early winter of 1919-20, which was, however, not so widespread and virulent as the previous epidemic of 1918, when the extraordinary death rate of 262.2 per 100,000 of the population resulted. After influenza the most important causes of death (omitting pneumonia, which was doubtless influenced by the influenza epidemic) were organic heart disease, cancer, and tuberculosis. The deaths from tuberculosis numbered 2,280, a rate of 78.7 per 100,000 of the population. The cities had a rate of 74.7, the towns of over 5,000 population 85.7, and the rural municipalities 81 per 100,000 of the population. The campaign against tuberculosis has received assistance from municipal activities and from voluntary societies, while useful educational work has been done by the Canadian Association for the Prevention of Tuberculosis. It is

suggested in the report that tuberculosis is one of the diseases in the prevention of which the Dominion Government should afford greater assistance to the provinces. The entire cost of tuberculosis work in Canada, with the exception of 10,000 dollars voted to the Canadian Association, is borne by the provincial governments. In regard to cancer, the number of deaths for the year was 2,464, giving a rate of 85 per 100,000 of the population, as compared with 16 in 1881. As elsewhere, the apparent increase in cancer mortality may be accounted for to some extent by improvement in diagnosis and more satisfactory death records.

MENTALLY DEFECTIVE CHILDREN.

THE Birmingham School Board appointed a Special Schools After-care Committee as early as 1901; the Committee still exists, but for the after-care of the mentally defective only. The annual report for 1920 deals with the work of this Committee. During the past year 2,655 cases have been under care. Of these, 707 are doing remunerative work, 76 were dismissed as incapable, 625 are living at home and doing no paid work, 163 improved so much that they could be transferred to ordinary schools, 25 went to schools for physical defectives (mostly to schools for the deaf), and 271 now live in institutions for the defective. No less than 480 (25 per cent.) have been lost sight of, and most of them before the age of leaving school. The percentage of those in employment has fallen from 45 per cent. in 1920 to 32 per cent. during the past year. This is the lowest percentage of employed cases since 1912, but it is considered good under the abnormal conditions of trade, which affects these young persons first. The report shows a small increase in the marriage rate; there have been five new instances of the birth of illegitimate children, and several girls are said to be leading irregular lives. The proposed limitation of provision for these mental defectives after school years under the economy circular of August, 1921, led to the production of conclusive proof that it was far more economical to the nation as a whole to maintain certain types of mental defectives in suitable institutions than to be dealing with them periodically in prisons, workhouses or maternity homes. The circular which proposed the reduction of accommodation was eventually withdrawn. Cases are cited which show the great advantage of the segregation of the dangerous mental defective. The Committee has under consideration the provision of a workshop where employment could be found for a certain number of those who easily fall out of work and yet are able to do something.

INTERNATIONAL ASSOCIATION OF MEDICAL WOMEN.

A MEETING of the London Association of the Medical Women's Federation was held on October 10th with the president Dr. Louisa Martindale, in the chair. Lady Barrett, M.D. gave a report of the international meeting of medical women which was held in Geneva last month, at which eighty medical women were present, representing eighteen countries (A report appeared in the SUPPLEMENT of September 16th p. 111.) Lady Barrett stated that the idea of an international association of medical women had originated simultaneously here and in America. The Medical Women's Federation here had hoped to inaugurate an international association which should be composed of national associations, while in America an international association had already been started in 1919, composed of individual members from many countries of the world. At the request of the Americans the Medical Women's Federation of Great Britain drew up a draft constitution, which was to be presented to the Geneva Conference of 1922. The delegates from the Federation to this Constitution Committee were: Dr. Jau Walker (chairman of the committee at Geneva), Dr. Catherine Ghisholm, Dr. Christine Murrell (joint secretary to the committee and vice-president of the American International Association, 1919), Dr. Dickinson Berry (joint secretary to the committee), Lady Barrett (president of the British Federation). Lady Barrett said that there was considerable difference of opinion at the conference as to the basis of membership, but

that finally a compromise was reached. It was decided that membership should be on the basis of national associations of medical women, in some cases sections of medical women, and in a few instances individual medical women should be eligible.

SIR W. LESLIE MACKENZIE, M.D., LL.D., has been appointed for five years as the Crown representative for Scotland on the General Medical Council in succession to Dr. J. C. McVail, whose term of office expires on October 28th.

SIR ALFRED KEOGH, G.C.B., G.C.V.O., M.D., has been awarded the gold medal of the Institution of Mining and Metallurgy "on the occasion of his retirement from the rectorship of the Imperial College of Science and Technology, in recognition of his great services in the advancement of technological education, and as a mark of admiration and respect."

MOTOR NOTES FOR MEDICAL MEN.

BY H. MASSAC BUIST.

TAXATION.

The "Agreed" Recommendations.

Those motoring organizations that have been in consultation with a view to the production of what may be called an agreed, or unified, recommendation in regard to the re-casting of the taxation scheme in respect of the ownership of motor vehicles in this country have sent their report to the Ministry of Transport. It is a document with which the members of the medical profession are very intimately concerned. The recommendations are on behalf of the Society of Motor Manufacturers and Traders, the Scottish Motor Trade Association, the Motor Agents' Association, the Motor Trade Association, the Association of British Motor Manufacturers, the Institute of British Carriage Manufacturers, and the British Cycle and Motor Cycle Manufacturers' and Traders' Union, as well as of the Royal Automobile Club, the Royal Scottish Automobile Club, the Automobile Association and Motor Union, and the Auto-cycle Union, which four bodies, it is asserted on the cover of the memorandum, represent "all classes of motor vehicle owners in Great Britain." For a point of some accuracy it will be observed, however, that the Commercial Motor Vehicle Users' Association is not represented. That is an organization the members of which own some tens of millions of pounds' worth of road stock. The utility motor vehicle users of this country will have nothing whatever to do with the recommendations of the report. It is suggested that the registration book has failed to serve any useful purpose, and that it should be abolished, thereby saving a proportion of present administration costs; with this, doubtless, all will agree. It is further suggested that annual car licences should be issued to expire on any date; this, again, is a reform greatly needed. Another recommendation is that, with the proposed reduction of the registration tax, there would be little incentive to take up quarterly or monthly licences, and that this would result in further administrative economies. Other recommendations are:

- (a) A flat rate duty per gallon to be imposed on all imported motor spirit to provide the bulk of the required revenue, the remainder to be derived from a reduced tax on the vehicle.
- (b) All imported liquid hydrocarbons to be taxed at the port of entry on "motor spirit content" (the term is defined in Part 4).
- (c) Motor spirit for motor boat, aviation, or any purposes other than for motor vehicles, to be supplied duty free on a permit system, such spirit, if desired by the authorities, to be coloured suitably.
- (d) No duty to be imposed upon motor spirit obtained from raw materials produced in Great Britain.
- (e) No rebates of duty to be granted to any user of motor spirit.
- (f) Vehicles, other than those with internal combustion engines, to be taxed on the present method.

It is noted that any proposal submitted must be such as to secure a revenue equivalent to that produced in 1921-22, exclusive of the receipts in respect of licences for horse-drawn vehicles, drivers' licences, and penalties. Nothing is said as to the cost, nor are specific details furnished concerning what is called a simple permit system whereby fuel for motor boats, aviation, and such-like purposes, is proposed

to be duty free. Nor is the very practical question, always asked on behalf of the Excise authorities, answered; yet it was understood that practical politics was to be the sole purpose of these negotiations. Frankly, I am extremely disappointed that there is no specific constructive paragraph showing how the Excise authorities are to solve their problem in respect of motor spirits distilled from crude oils imported into this country. Benzol, and such-like motor spirit produced in this country, is to be duty free. But under this head I fail to discover any solution of the problem of the lucky *versus* the unlucky motor vehicle owner. For example, according to this system, the man who secures home-produced motor fuel, which would be duty free, would benefit; but those who resided in neighbourhoods where such supplies were not available would be among the unlucky ones who were paying for the roads which "the other fellow" would be enjoying practically free of cost to himself. When it comes down to practical details, there are only two schemes, submitted on page 11 of the memorandum, and both concern approximate revenue. According to scheme A, the motor spirit duty would be at the rate of 5d. a gallon, and the registration duty 2s. 6d. per horse-power.

Horse-power Rating would remain Unaltered.

We know that the Treasury rating of horse-power would continue as at present, because the Society of Motor Manufacturers and Traders has discussed that matter, and has decided that no useful purpose could be served at this juncture by altering the basis of the Treasury rating, no matter how unsatisfactory it may be, since we should only leave the ills we have to fly to others that we know not of. Under scheme B in the report, the motor spirit duty would be 4d. a gallon, and there would be 75 per cent. reduction on the horse-power tax, which would be approximately 5s. per horse-power. Under both these schemes the man who secured benzol, or other home-produced fuel, would escape respectively 5d. and 4d. a gallon duty. Whereas when last a fuel tax was in vogue medical men were exempt, it is specifically laid down in these recommendations that there shall be no rebates nor exemptions other than those already specified under the reference permits. Inasmuch, too, as the ratio of horse-power tax that would be paid by medical men owning various classes of vehicles would be just the same as that which, it is alleged, is generally complained of at present, it would follow that the owner of a Ford car, for example, by comparison with the owner of, let us say, one of the new small 8-h.p. (Treasury rating), 4-cylinder, overhead valve, small cars, would be at the same disadvantage as he labours under at present, because Treasury rating would be the basis of both rates of duty. Further, the economy of the modern British or French built vehicles under the head of fuel, by comparison with the Ford, would also continue to give the advantage to the product that represented the latest higher standard of engineering efficiency. Moreover, it is frankly admitted on behalf of the recommendations that a large number, including small-car owners, would pay considerably less under the new heading of taxation than they do at present; and that, inasmuch as the gross amount of revenue to be reaped by the Treasury must be the same, those who used their cars considerably more than, say, 3,000 miles a year would have to make up the difference. Being interpreted, that means that the members of the medical profession in general would contribute more than any other section of motor users towards relief proposed to be accorded. The scheme represents, incidentally, a return from a single tax, as at present, to a dual tax. Take it for all in all, though it is called an agreed scheme, it must not be understood for a moment that it represents the views of all the members, or even necessarily a majority of the members, of the organizations that jointly put it forward. Not more than one member in three of the A.A. has troubled to back it by referendum. Certainly it will meet with much opposition.

FUEL, TYRE, AND CAR COSTS.

A great change has come over the spirit of motoring during the autumn. Fuel costs have come down from 5½d. a gallon, not owing to any immediate possibility of selling a gallon, nor petrol during the winter months at a lower cost, but more petrol during the winter months at a lower cost, but chiefly because long-term contracts in respect of shipping and such-like costs contracted for at the height of the post-war boom have now lapsed; therefore matters are getting back towards normal. An even more important factor is the great increase in the market for the residuary products of

the distillation of crude oil. This growth of the fuel oil market, largely for the service of the world's shipping industry, is something which motorists have long had cause to desire; hitherto they have had to pay more for their petrol because the manufacturers were loaded with residuary products which had to be sold at a loss, at no profit, or at an inadequate profit. Therefore, the more the markets for the residuary products of crude oil distillation can be developed the lower will be the proportion of the total cost of engaging in enterprise of this sort, which has to be borne by the users of the more volatile products, motor spirit in particular.

Tyres Cheaper than before the War.

Simultaneously with this material cheapening of petrol, which really represents a reduction of the fuel bill by one-sixth, there have been notable reductions in tyre costs. The result is that trends to-day of post-war construction are marked by the best makers at about the same figure as obtained in 1914, with this notable difference, that for these corresponding sums—there is not 3s. 6d. per average size of tread difference—the post-war production is designed on such lines and made by such infinitely superior manufacturing processes, notably, the curing of rubber—that the cost to-day is at least two and a half times as great as was possible in 1914, and in most cases three times. The actual result depends very much less on luck than formerly. But, of course, it still depends largely on the manner in which the individual drives, alike as regards changing gear and the application of brakes, as well as in respect of his care in not running his tyres on to the points of tramlines, and so forth. Assuming he drives with judgement, however, the medical man should have at least two and a half times the tyre mileage with corded type covers that he had before the war with the fabric types then available. The vast progress that has been made in the curing of rubber since 1914 will be appreciated by anyone who will follow my example and visit the laboratories instituted for rubber research. The system of construction is better and the product much more durable. The inner tubes, now sold by most of the leading makers at approximately half the price at which they were marketed in 1914, are better tubes. Therefore, under the heading of tyre costs the medical man's motoring bill is reduced from now onwards to a figure lower than any he has previously experienced. An illustration may be taken from the Dunlop Company's list, citing the popular size tyre, 815 by 105. When the inferior canvas cord groove type only was available in 1914 the cost was £5, whereas to-day the Dunlop clipper cord type, which is a better article, costs £4 13s. This year's price for this size Dunlop cord type of the same size has been £7 2s. 9d., whereas to-day it is £5 3s. 9d. only.

Insurance and Capital Outlay.

In regard to motor cars, while the Paris show has been held, nevertheless it is a fact that we shall not realize fully what motor car marketing enterprise amounts to in the gross for next year until the opening at Olympia, Kensington, and the White City, Shepherd's Bush, London, on November 3rd, of the International Passenger Car Show, of which I propose to give some account in the JOURNAL of November 4th. A large proportion of the chassis, and of even complete cars, staged in the Grand Palais in Paris this month were the identical vehicles which were shown there last year. By contrast, there will scarcely be an exception to the rule that this autumn's products alone will be staged at the London exhibition. Further, the reductions in the cost of labour and of raw materials, and progress alike in design and in manufacturing methods and equipment, have rendered possible great reductions in the cost of cars. Apart from the cost of garaging, the other chief items of cost in respect of motoring are insurance and taxation. Taxation is referred to above. Apparently the insurance rates are not likely to fall as have fuel, tyre, and car costs, but, inasmuch as cars are to be marketed at very much lower prices, capacity for capacity, it follows that the actual sums of money on which insurance will have to be paid will be reduced automatically and appreciably in respect of those who acquire cars from now onwards. But insurance rates must continue to rule high as long as average driving results inevitably in the high proportion of claims enured; and there is as much car stealing as has been experienced since the war. If we can reduce these adverse factors we shall find notable reductions in the cost of insurance.

England and Wales.

NATIONAL MILK CONFERENCE.

A NATIONAL Milk Conference was held at the Guildhall, London, on October 16th, 17th, and 18th. It was called by the National Clean Milk Society, supported by certain other bodies, including the British Medical Association (which was represented by Dr. T. W. H. Garstang), the Royal Institute of Public Health, the Royal Sanitary Institute, and the Federation of Medical and Allied Societies, as well as a number of agricultural organizations. On the first day of the Conference the matters under discussion were in the main of agricultural interest, such as the breed of cattle in relation to quantity, chemical composition, and cost of milk production, and the feeding of dairy cattle in relation to this last factor. On the subsequent days discussions took place on bovine tuberculosis, the chemical composition of milk, pasteurization, and food values. The Conference was attended by some two hundred representatives, including several visitors from the dominions and foreign countries, three or four of whom came as representatives of their Governments.

Lord Astor, in an opening speech, declared that neither the milk industry itself nor the Ministry of Agriculture had in the past realized the importance of milk as a beverage. Uncontaminated milk was as important, in view of the health of children, as an uncontaminated water supply. Every year the milk trade lost thousands of pounds owing to premature souring, which was the result of uncleanly methods. Sir A. Griffith-Boscawen, Minister of Agriculture, who took the chair at the first session, said that the nations which consumed most milk per head of population were the most virile, and the consumption of more milk per head would be a great advantage to this country. A later speaker gave figures to show that in New York twice as much milk was consumed per head as in London. Among the papers read on the first day one was by Sir Stewart Stockman, chief veterinary officer and director of veterinary research at the Ministry of Agriculture and Fisheries, who dealt with epizootic bovine abortion and its effect upon milk supply. This contagious disease of cattle, due to a non-motile bacillus, has been specially studied at the Ministry's veterinary laboratory with a view to elaborating a method of protective inoculation, for which good results are claimed. In an area where the disease was prevalent, out of 493 test animals vaccinated 32 (or 6.5 per cent.) afterwards aborted, while of 265 animals not immunized, and left as controls, 101 (or 38 per cent.) aborted. In reply to a question, the speaker said that there was no evidence whatever to support the view that if milk which happened to contain the abortion bacillus was drunk by pregnant women it might lead to human abortion; tests had been made with the blood of pregnant women, and no sign of any agglutination reaction had been discovered.

The remaining subject at the first session was the production of clean milk, in particular the education and equipment of the dairyman. Dr. R. Stenhouse Williams, Research Professor in Dairy Bacteriology, University College, Reading, in opening the discussion, described the clean milk campaign, which had made considerable progress in some parts of England. More "Grade A" milk from tuberculin-tested cows was sold in Reading than in any other town in the country. There were five centres in Reading in which this milk could be secured, at one penny a quart above the ordinary price. Another town well-advanced in the movement for clean milk was Leicester, where the authorities had announced that no contracts for milk for hospitals or schools would be accepted unless the milk was "Grade A," for which an extra threepence a gallon would be paid. The speaker feared the effect of Government regulation upon the clean milk movement. It seemed likely that, following on recent legislation, "Grade A" licences would be granted simply on veterinary inspection of the cattle, so that the "Grade A" farmer who resorted to the tuberculin test would get no official credit for the work he had done. Mr. Wilfred Buckley, C.B.E., who was presiding over the Conference at the time, said that no official statement had been issued by the Government as to the nature of the forthcoming regulations, and he understood that the Ministry of Health had under consideration the requirement of the bacteriological count as well as the veterinary inspection. Some sharp divergence of opinion was manifested by various medical officers of health who took part in the subsequent discussion as to the extent to which contamination of milk occurred in the home. Dr. Nash denied emphatically that the

to was responsible for any considerable part of the termination.

A report of the later sessions, over which Sir Alfred Mond, Count Elvedon, Sir Walter Fletcher, and Sir George Wyman presided, will appear in our next issue.

NEWCASTLE-UPON-TYNE AND NORTHERN COUNTIES MEDICAL SOCIETY.

The first meeting of the session was held in the Royal Victoria Infirmary on October 5th. Professor Stuart McDonald, re-President, was in the chair, and about a hundred members were present. The first part of the meeting was a demonstration of cases and pathological specimens. Cases were shown by Drs. W. E. Hume, Horsley Drummond, George Hall, Messrs. H. Bruntton Angus, S. S. Whillies, R. J. Willan, and Hamilton Drummond. The pathological specimens were arranged by Mr. W. E. M. Wardill, curator of the museum of the Durham University College of Medicine. Later in the evening a most interesting paper was read by Mr. F. C. Pybus "Some surgical aspects of dyspepsia." The paper will appear in full in the *Newcastle and Northern Counties Medical Journal*. During the meeting the sad news was received of a death of the President of the Society, Dr. Lachlan G. Fraser, and a vote of sympathy with the widow and family was passed. The Society meets monthly during the winter session, and in addition to the ordinary meetings two clinical and pathological meetings have been arranged for the convenience of country members at 4.30 p.m. on October 25th and January 24th. The annual address is to be delivered on December 7th by Sir Humphry Rolleston, President of the Royal College of Physicians of London, on "Reflections on high arterial blood pressure." The annual dinner will be held the same evening, when Sir Humphry Rolleston will be a guest of the Society. On February 1st an address on "Diagnosis in surgery" will be given by Mr. D. P. D. Wilkie of Edinburgh.

LONDON HOSPITAL DINNER.

The London Hospital Old Students' dinner was held at the Rocadero Restaurant on October 12th. The chair was taken by Sir Arthur Keith, F.R.S., and he was supported, amongst others, by Lord Knutsford (Chairman of the Hospital), Sir Hugh Rigby, Sir John Lymington-Thomas, Sir William Lister, Sir James Dundas-Grant, Mr. T. H. Openshaw, Mr. James Gordon, and Dr. Robert Hutchison. The principal guest was Surgeon Vice-Admiral Sir Robert Hill, K.C.B., K.C.M.G., Medical Director-General of the Navy. The gathering was large and enthusiastic, each generation of old students being well represented, while the hospital staff turned out in force. One factor more than another could be held responsible for the success of the evening, that should be the method adopted in arranging the tables. So far as possible each table was given up to one generation of old students, so that it was practically certain that any man attending the dinner, even if he had lost touch with his old school for years, must find himself seated among old friends. To the honorary secretaries, Messrs. Souttar and Lindsay, more than an ordinary tribute of praise is owing for the art displayed in so skilfully arranging such a numerous gathering. As should be on an occasion such as this, the evening was devoted more to the renewing of old friendships—the harking back to the good old days—rather than to listening to a number of set speeches. After the toasts of "The King" and "Queen Alexandra, Patron of the Hospital" had been duly honoured, Sir Arthur Keith proposed "The London Hospital." In a humorous manner he explained the circumstances which brought about his appointment many years ago to be senior demonstrator of anatomy at the princely salary of £100 a year. In happy vein he developed his theme to show that not only was the research worker starved by the totally inadequate reward offered for his labours but the aspirant to the hospital staff was similarly handicapped in his early years. He had to shoulder an utterly unfair burden in being forced to devote so much of his time to the gratuitous service of his hospital. Not only had the staff themselves to carry a share of the burden of sickness in London, they had at the same time to satisfy the by no means modest claims of the West End landlord. He appealed to the wealthy citizens of London to give generously and freely towards the endowment of medical education that the perpetual war against disease might be waged successfully by the combined efforts of clinical and laboratory research workers. The toast was supported by Sir Arthur Keith and by Mr. Openshaw, who said that no man

had so closely followed in the footsteps of John Hunter as had Sir Arthur Keith. The health of the chairman was briefly proposed by Dr. Robert Hutchison.

KING'S COLLEGE HOSPITAL WAR MEMORIAL.

On October 11th Viscount Hambleden, chairman of the hospital, declared open a war memorial pavilion on the athletic ground of King's College Hospital Medical School. The tablet he unveiled bears the inscription, "Dedicated to the memory of the Students of this School who fell in the Great War—1914-1918." The history of the war memorial was recounted by Mr. L. V. Cargill, senior ophthalmic surgeon. Lord Hambleden in the course of his address said that of all the wonderful organizations created during the war none were more remarkable than the medical services of the two great fighting forces. The services of the medical men who joined the armed forces could never have been rendered had it not been for the work of the voluntary hospitals and their medical schools in former years. "We appreciate to the full," he said, "the work of the Regular officers of the R.A.M.C. and the powers of organization which they showed. They called upon, and not in vain, the services of men who had been trained for ordinary civilian work, who turned their knowledge and capacity to the service of their country in the war. We can surely be proud as King's College men of the part which old students, our honorary staff, and our nurses played, and especially are we proud of those who made the greatest sacrifice of all and gave their lives to the cause of their country and their fellow-men." A vote of thanks to Lord Hambleden was proposed by the Dean, Dr. H. Willoughby Lyle, and seconded by Dr. H. A. Lucas.

MIDWIVES AND CHLOROFORM.

A special meeting of the Central Midwives Board for England and Wales was held on October 11th, Sir Francis Champneys presiding. Three cases adjourned for reports and eight fresh cases were dealt with; six midwives were removed from the roll. At the ordinary monthly meeting, which was held on October 12th, a letter was read from the clerk of the Middlesex County Council reporting that the County Council was not in a position to find a prima facie case under Section 8 (2) of the Midwives Act, 1902, against a midwife who had administered a "whiff of chloroform," and again asking for the Board's views as to the desirability of a midwife administering chloroform. It was agreed to reply as follows:

"That the Board will express its opinion as to whether or not the use of a drug by a midwife is justified when it has a concrete case before it, and is aware of all the circumstances attending the administration or the use of such drug. The Board sees no reason why the midwife should not be reported in order that the Board may consider the question on a concrete case."

Certain lecturers and teachers were approved, and the meeting terminated.

Scotland.

PRESENTATION TO DR. J. R. CURRIE.

Dr. J. R. CURRIE, of the Scottish Board of Health, was entertained to dinner in the hall of the Royal College of Physicians, Edinburgh, by a number of medical colleagues on the occasion of his impending departure to take up the duties of professor of preventive medicine in Queen's University, Kingston, Ontario. Dr. John Playfair presided, and the company included Sir James Hodsdon, Sir Leslie Mackenzie, Sir Robert Philip, Dr. Norman Walker, Dr. A. K. Chalmers, Dr. J. R. Drevet. Sir Robert Philip proposed the health of the guest, and Dr. Currie, in reply, said that the health of a medical officer had changed greatly in the ten years since he was medical officer for the counties of Fife and Kinross. At that time the medical officer dealt with the impurity of streams and water supplies, removed cases of infectious disease to hospital and dealt vigorously with infection, and was very wise on the subject of drains. Nowadays tuberculosis alone had broadened into a special subject by itself; they had added the hygiene of the young child to the hygiene of the school child, and included the hygiene of the infant and the child unborn. Preventive medicine should go on and take a grasp of the social questions of the hour and of the future, and it was now said that all medical teaching should have a preventive bias. Dr. Norman Walker, in

presenting Dr. Currie, on behalf of his Scottish friends, with a silver bowl and a silver tea service, communicated upon the success of the work which Dr. Currie performed in connexion with the Scottish Emergency Committee on medical service during the war.

LINKS BETWEEN NATURAL HISTORY AND MEDICINE.

The inaugural address to the students of the Anderson College of Medicine, Glasgow, was delivered on October 10th by Professor J. Arthur Thomson of Aberdeen, who took for his subject "Some links between natural history and medicine." In olden days, he said, every medical practitioner was a bit of a naturalist, using plant simples and animal simples. The leech, his pocket companion for centuries, became synonymous with doctor. When from the animal prescriptions were subtracted those that seemed quite superstitious, there remained some which were reasonable and a few which suggested glimpses of modern discovery. Thus decoctions of ants, rich in formic acid, and diets of snails, the poor man's oysters, might well have useful results, and the use of snake's bile as a counteractive to the venom had been confirmed by modern research. There was no finer instance of the help that zoology could give to medicine than the contribution made by Dr. R. T. Leiper, a Glasgow graduate, to the life history of billiardzia. One of the characteristic features in the history of twentieth-century zoology and medicine had been the rise of protozoology into a science almost as important as bacteriology. Along with protozoology had developed medical entomology, for most of the formidable protozoa were carried and disseminated by insects. Greatly to the credit of zoology and medicine, working hand in hand, had been the elucidation of the part played by the mosquito in spreading malaria and of the tsetse fly in spreading sleeping sickness. It might be that a correlation of the facts of artificial parthenogenesis, the phenomena of regenerating lost parts, and the formation of gall growths, would throw some gleam of light on the dark problem of cancer. Again, there was great suggestiveness in the modern studies of senescence in animals and the various ways in which this was counteracted by processes of rejuvenescence. Zoology had been a trusty ally of medicine in the past, and the actual alliance was now firmer than ever.

HEALTH AND HOUSING IN DUNDEE.

The Dundee census report was dealt with in our issue of August 26th (p. 400). The principal statistics for 1921, as given in his annual report by the medical officer of health, Dr. W. L. Burgess, include the following: The corrected death rate was 15.8, the infantile death rate 114 per 1,000 births, the birth rate 26.5. The death rate from pulmonary tuberculosis was 1, from all forms of tuberculosis 1.35, and from the principal epidemic diseases 1.09. The infant mortality was the lowest on record, as was also the tuberculosis death rate. There was very little epidemic disease; smallpox was entirely absent, and of enteric fever there were only seven cases. Dr. Burgess complains that notification of puerperal fever is not efficiently carried out by medical practitioners, partly, he observes, because the disease is not clearly defined. There were 193 notifications of ophthalmia neonatorum, being 1 in 23 births, against 1 in 19 births in the previous year; complete recovery took place in every case. Notification of tuberculosis is stated also to be very defective; of the 474 recorded cases, no less than 203 were detected by the tuberculosis officers, only 164 were notified by doctors, and 54 were brought to notice by the death returns. Dr. Burgess is doubtful whether any treatment should be carried out at the tuberculosis dispensary, and inclines to the view that its functions should be diagnosis, examination of contacts, supervision and education of patients, and the making of arrangements for institutional treatment, the work being supplemented in the homes of the patients. Child welfare work in Dundee suffered very seriously from the industrial depression, but considerable good was done in granting relief. Dr. Burgess holds, however, that, notwithstanding co-operation between the authorities interested, there was undoubtedly overlapping in this. Housing is discussed in relation to the society conditions of Dundee. A tremendous number of women are employed in industry, and have only an hour's interval to prepare and consume a meal, too often of tea and tinned food. Many of them are married and have to arrange for the care of their children, whom they may have to take to day nurseries. Also they dislike travelling any great distance to and from their homes in the dark of winter, while tram fares would add considerably to their outlays. In these

circumstances their houses must be near their work, only small rent can be paid, and small "tenement houses," as the term is used in Scotland, seem to Dr. Burgess to be properly permissible to meet the situation. Housing schemes have done much for the "middle" working class, but not for the "lower" working class areas, and it is stated that not a single family living in the slum areas has benefited by the new housing schemes.

Ireland.

At the annual election of officers of the Pharmaceutical Society of Ireland, held on Tuesday, October 10th, Dr. A. J. Barnes of Dublin was re-elected President for the ensuing year.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

During the session 1921-22 the Academy consisted of 17 Fellows, 8 Members, and 20 Student Associates, numbers which are almost identical with those of the previous year. The accounts for the session have been audited, and the balance sheet shows the financial state of the Academy at the close of the session. The income during the year amounted to £441 2s. 5d., and the expenditure to £365 7s. 4d., thus leaving a balance to be carried forward to the next session of £75 15s. 1d. Professor Oskar Frankl again visited Dublin during the year, and he accepted the invitation of the Council to lecture before the Academy. Two lectures were given on April 25th and 27th, in the theatre of the Royal College of Surgeons, and both were well attended. During Professor Frankl's visit the Council heard of the hardships to which medical men in Vienna were subjected in consequence of the financial position there. So bad had things become that it was feared that owing to lack of funds the Medical Society of Vienna would have to close its libraries during the coming winter. The Council decided to open a subscription among the Fellows and Members of the Royal Academy of Medicine in Ireland; a sum of £45 10s. 6d. was collected and was sent as a donation to the library from the Academy. For this gift the sincere thanks of the Society have been sent by its President, Professor Eiselsberg, its Treasurer, and Professor Frankl.

A permanent contract has been entered into with Messrs. Cahill for the publication of the Academy's journal, and at a special meeting held on April 12th, 1922, the title of the journal was changed to *The Irish Journal of Medical Science*. Unfortunately, owing to the destruction of the premises of Messrs. Cahill by fire, the regular publication of the monthly numbers of the journal has been somewhat interfered with, but it is hoped that this difficulty will shortly be overcome. An important step has been taken by the establishment of an Obstetrical Research Committee in connexion with the Section of Obstetrics and Gynaecology. It is proposed that this Committee should prepare statistics and make collective investigations. Dr. Louis Cassidy, Master of the Coombe Hospital, Dublin, has been appointed secretary of the Committee, and the Council has voted a sum of 5 guineas towards the expenses.

The Council records with sincere sorrow the death during the session of two valued Fellows of the Academy, Sir Joseph Redmond and Professor Edward Taylor. Dr. Joseph Michael Redmond was one of the original Fellows of the Academy, and in 1907 and 1908, when President of the Royal College of Physicians of Ireland, he was President of the Section of Medicine. Several communications by him have appeared in the *Transactions*. Professor Edward Henry Taylor, who had been President of the Royal College of Surgeons in Ireland for just two years at the time of his death, was for many years an active member of the Section of Surgery, of which he was President when he died.

The Council is glad to be able to record a continued progress of the Academy. During the session twenty-five sectional meetings were held, at which the attendances were: Fellows 494, Members 30, Student Associates 164, and visitors 199.

ROYAL VICTORIA HOSPITAL, BELFAST.

The inaugural address was delivered at the opening of the winter session by the Marquess of Londonderry, the Minister for Education for Northern Ireland, in the Edward VII Memorial Hall of the hospital on October 12th. The Chairman of the medical staff, Professor Sinclair, F.R.C.S. Eng.,

said that Lord Londonderry had no need of any introduction to an audience in their province; he was indefatigable in visiting schools of all kinds, and in making himself directly acquainted in a practical manner with all forms of education. Perhaps there were one or two facts that he might mention to him, and he did so with a pride that was shared by all the members of the medical staff. Their medical students in all now numbered nearly 700, and this constituted them in respect of numbers the fourth largest school in the kingdom. Of the medical staff of the hospital, eight held professorships or lectureships in the university. Their board of management, under the chairmanship of Professor Lindsay, was enlightened, and was most liberal in meeting all their demands that tended to promote the welfare of the patients and the advancement of medical education. He assured Lord Londonderry of their gratitude and appreciation of his kindness in coming to open the session when there were so many calls on his time and energy. Lord Londonderry, who was received with the greatest heartiness by the students, expressed his pleasure in coming and thanked them for their welcome. He knew how much Lord and Lady Pirrie had done for their hospital and the value this hospital was to Ireland. He was especially interested in the clinical teaching, as it was part of the university work. It was his desire to widen the present avenues to the university and to open up more; the drawback in the past was the lack of opportunities for everyone to equip themselves intellectually for the battle of life. His primary care was for the young: his audience were of an age to know their responsibilities; those for whom he worked in primary and secondary schools were not of an age to do so; and he hoped that in time to come, as their education system became more and more perfect, he might be allowed to address on some future occasion another audience in that chamber even better equipped for their advanced studies that now occupied them. He urged them and all students to fit themselves for and to interest themselves in all that was passing around; it was a duty to themselves and to their province and to their Empire. Dr. McKisack proposed and Mr. Mitchell seconded a most hearty vote of thanks to Lord Londonderry for his enlightened and stimulating address, and this was conveyed by the chairman.

VITAL STATISTICS OF NORTHERN IRELAND.

The first quarterly return of marriages, births, and deaths issued by the Government of Northern Ireland has been published.¹ The population of Northern Ireland in the middle of 1922 was estimated to be 1,284,000, inclusive of military. The number of marriages registered during the fourth quarter of 1921 was 1,855, representing an annual rate of 5.8 per 1,000 of population. During the quarter ending March 31st, 1922, 7,639 births were registered in Northern Ireland, equal to an annual birth rate of 23.8 per 1,000 of the estimated population; in England and Wales the corresponding birth rate during the quarter was 22.2. The deaths registered during the first quarter of the present year numbered 6,422, representing an annual death rate of 20 per 1,000; the corresponding mortality in England and Wales was 17.7. In the county boroughs and urban districts, which contained nearly one-half of the total population, the equivalent annual death rate for the quarter under review was 28.8 per 1,000, and the birth rate for the remainder of Northern Ireland was 20.7. The death rate in the county boroughs and urban districts was 22.1 per 1,000, and the corresponding rate for the remainder of Northern Ireland was 19.2. The urban mortality from the principal epidemic diseases recorded during the quarter was equivalent to a rate of 1 per 1,000, the death rate from these diseases for the remainder of Northern Ireland being 0.6.

Mauritius.

THE CASE FOR SANITARY REFORM.

Nearly two years ago the Secretary of State for the Colonies commissioned Dr. Andrew Balfour, C.B., C.M.G., to visit the island of Mauritius for the purpose of investigating its sanitary condition. The Report² has now been issued, and discloses the extent and urgency of the reforms which should be

instituted. The island has an area of fully 700 square miles and a population of 376,000, of whom about 10,000 are whites, mostly French. The working classes, who are in great proportion descendants of liberated slaves, are stated to be highly intelligent. The population, however, is very heterogeneous. The density of population is over 500 per square mile, and the death rate is from 32 to 35 per 1,000, but in 1919 an influenza epidemic raised it to close on 65 per 1,000. In 1920 the rates in different districts ranged from 23 to over 40 per 1,000. Dr. Balfour devotes the earlier part of his report to communicable diseases. Dr. J. F. Kendrick had made, on behalf of the Rockefeller Foundation, and not very long before Dr. Balfour's visit, a survey of the island in relation to ankylostomiasis, and estimated that about 226,000 persons—three-fifths of the population—were infected. For prevention of infection of influenza amongst contacts value was attached to a measure advocated by Dr. J. A. Taylor of the Uganda Medical Service. It consisted in the application every three hours on the tongue of contacts of two or three drops of a mixture of equal parts of ordinary tincture of iodine (B.P.) and native honey. The accommodation for leprosy Dr. Balfour condemns unsparingly. The single asylum, he says, is "a disgrace to the colony." Against malaria much good work has been done in giving effect to the recommendations of Sir Ronald Ross, who had visited the colony a number of years previously. Malaria, however, still ranks first as a destroyer of life in Mauritius. Tuberculosis comes next, being spread by faulty housing, poor food, unsuitable clothing, poverty, alcoholism, and predisposed to by ankylostomiasis. As regards alcoholism, a commission, appointed by Sir Hesketh Bell in 1919, reported on the paramount importance of combating the increasing peril. Conflicting interests, however, are powerful. The State derives large revenue from the liquor traffic; the distillers sell their ruin to the trade; the traders retail it to the public; and the sugar planters supply the distillers with the molasses. The retailers are mostly Chiuamen. The commission did not recommend immediate prohibition, but vigorous control, and the manufacture of a light drink, such as Kafir beer. Dr. Balfour hopes also that what is known as the Durban scheme will be adopted, its main feature being the vesting in the Town Council of a monopoly for the entire control of the manufacture and sale of the native beer, all profits going to a special "Native Administration Fund" for the general well-being.

Under the heading "Medical facilities" there is consideration of hospitals,

maternity and schools. "Sanitary matters are more important than the medical and inspectorial staff, water supply, collection and disposal of excreta and general refuse, solid and liquid, slaughterhouses, meat markets, bakeries, milk supply, washing and disinfection, offensive trades, housing and town planning, schools, prisons, quarantine, and so forth. In short, nothing relevant appears to have been overlooked by Dr. Balfour, and he amply demonstrates that in practically every direction there are many defects. He makes a series of recommendations for reorganization of the medical and health department of the colony. An important step already taken is the appointment of a competent consulting sanitary engineer, who had reached the island before Dr. Balfour left. The scheme has obviously been thought out with care and knowledge, and though the total salaries suggested amount to fully £30,000 instead of £10,000 as at present, it is urged that they relate really to emergency conditions. In addition qualified sanitary inspectors are required, district mosquito brigades, improved equipment and increase of the staff of the bacteriological laboratory. In short, the question is fundamentally financial. Present-day knowledge of disease prevention is capable of being effectively applied to the numerous difficulties that have to be overcome. The existing conditions are appalling, and are forcibly described and photographically depicted by Dr. Balfour. A general improvement and development fund of ten million rupees had already been voted by the Council of Government, and an important part of the Commissioner's duty was to advise as to the spending of it. The task would have been easier if the sum had been larger, but the fund as invested yields Rs.750,000 a year. Of the measures needed for sanitary improvement thirteen are bracketed as equal in importance; they include general antimalarial measures, sanitation of Port Louis, various improvements in sewerage and scavenging, abolition of certain slum areas, improvements in milk supply and water supply, bacteriological laboratory establishment and

extension, and microscopos for hospitals and dispensaries. In respect of soil sanitation, there is to be co-operation between the Mauritius Government and the Rockefeller Foundation. About the fundamental economy of the whole proposal there can be no doubt. Dr. Balfour writes regarding Mauritius: "It is a marvellously fertile island, and the climate for the greater part of the year is delightful; but it has drifted into a state which is inimical both to efficiency and industry, and has, with good reason, gained a reputation which repels those who might otherwise visit it, either for purposes of commerce or pleasure." The report shows how that bad reputation may be mended, and it is for the authorities to give serious heed to the advice which they have received from their Commissioner.

Correspondence.

THE DIFFERENTIAL DIAGNOSIS OF SMALL-POX AND CHICKEN-POX.

SIR,—At the season favourable for the spread of small-pox, of which 21 recent cases in and near London have yielded 7 deaths (several at first were taken for chicken-pox), it may be of service to utter a reminder and to mention that the diagnostic criteria which have proved in practice to be the most reliable in differentiating some 500 cases of chicken-pox, mostly adults, from among about 11,000 cases of small-pox and similar diseases in London during the last twenty years are four in number—namely:

1. The presence or absence of marked general prostration in the early stages.
2. The relative density of the eruption on irritated surfaces.
3. The relative depth of the lesions in the skin.
4. The progressive maturation of the lesions.

As any febrile attack, however mild, may in reality be small-pox, every such illness calls for an examination of the skin and buccal mucosa for linemorrhages, papules, poeks, or other blemish, in order to prevent the escape of a case which, however trivial in itself, may yet occasion many fatalities.—I am, etc.,

London, W., Oct. 16th.

W. McC. WANKLYN.

PSYCHO-ANALYSIS.

SIR,—As Silas Wegg "dropped into poetry" only on being pressed, so unwillingly I feel I must "drop into print," for if Dr. McBride's letter in your issue of October 14th does not receive some reply the silence might be construed as consent, which is by no means the case.

Your correspondent desires that psycho-analysts should give a "reasoned defence" of their position, and presumably this should take the form of a letter to you.

The thing is impossible. As well ask a disciple of Darwin to defend his position in a letter.

The word "psycho-analysis" connotes three distinct subjects—namely, (a) a method of mental examination, (b) a theory, and (c) a method of treatment. Which of these is to be defended? Let us concentrate for a moment on (b)—the theory. The theory of Freud deals with normal mind, abnormal mind, dreams, wit, folklore, ethnology, myths, aesthetics, the science of religion, etc. Once again I ask, Is the relationship of the theory to all these to be defended? Or, if in one instance only, which one?

A reasonable exposition on any one of these matters is impossible in a letter, but in book form there is no lack of detailed description. It would be an easy task to give a list of books on psycho-analysis. I would recommend, however, to anyone interested in Freud's theories to begin with Hart's *Psychology of Insanity*. The student should then read *The Interpretation of Dreams* by Freud. Afterwards he has many books to choose from, but he must not omit to read Freud's *Introductory Lectures on Psycho-analysis*, just published. If, having completed these studies, he disagrees with their teaching, let him give his reasoned argument.

As things are at present, what one often meets with is ignorant prejudice. Some time ago a man whose identity was at the moment unknown to me, as mine was to him, said to me that he was going to make a speech on psycho-analysis. I asked him if he knew anything about the subject, and he was obliged to confess ignorance. I do not know if the speech was delivered, but, if so, doubtless it was received with prolonged and great applause; this state of affairs is not rare. Assertion takes the place of argument, and if this

is all that is required I can also assert. I have no hesitation in saying that the theory of psycho-analysis throws a flood of light upon numerous cases of mental disturbance, not only in the severe types commonly called insanity, but in the so-called border-line states, numerous examples of which I see at my out-patient department at King's College Hospital. I would further assert that a large and increasing number of my colleagues agree with what I say.

Now, if any anti-Freudian who has seriously studied the matter will give us a book containing the results of his considered judgement, I can guarantee it will be received with sympathy and read with care, nay, even with avidity. Personally I do not like the Freudian theories. They are hurtful to my self-esteem and they offend my aesthetic sense, and if anyone can prove that they are wrong these emotional disturbances will cease in me. But the question is not what one likes, but what is true.

I hope Dr. McBride does not think I include him in the company of those who have not studied the matter. He knows best. I would, however, say to him and to Sir Clifford Allbutt, to whom he refers, a modification of the words of Gamaliel:

"For if this counsel or this work be not of the truth it will come to nought, but if it be the truth ye cannot overthrow it, lest haply ye be found even to fight against the truth."

—I am, etc.,

R. H. STEEN, M.D., F.R.C.P.

City of London Mental Hospital,
Oct. 16th.

SIR,—It is not without provocation that I write, for I have been reading the report of the proceedings at Glasgow, particularly in regard to the discussions of "psychotherapy." Where I got facts derived from experience I was content, but all too frequently I had the impression of being plunged into that style of high-sounding jargon devoid of any scientific thought that reminded me of the doctors of Molière.

I propose, however, to deal with these papers not by criticizing them point by point, but by taking the subject at other bearings so as to show the invalidity of the foundation on which this entire superstructure rests.

Psycho-analysts have brought themselves to a point at which they depend on Freud as the old schoolmen acknowledged the authority of Aristotle precisely in those parts of his philosophy where the great Stagirite was weakest. Galileo disposed of that worship by his experiment of dropping his two pellets from the leaning tower of Pisa, and by putting mechanics on a sane basis he prepared the scientific basis of our modern world. I have proposed to render a similar service to psychology.

Suppose that we were able to formulate what, by an analogy from chemistry, we might term the elements of thought, and that, having given such elements, we could show that by the syntheses of these all forms of psychic movement, the simplest and the most complex, could be exhibited, would we not have the master key to all psychology? It leaps to the eyes that it would be so. But that is precisely the problem which I set before myself and wrestled with for twenty years, until, at length, I was able to formulate these elements, or, as I have called them, the "fundamental processes of the mind."

Space does not permit me to enter into detail as to these fundamental processes, but one of them is association. That is not, of course, the only fundamental process, for, otherwise, no mechanism of mental activity could be demonstrated, whereas the manner of functioning of these processes corresponds to the working of the brain, which may be taken as the living diagrammatic form of the whole complex of the movements.

Now I wonder how many, even of ardent Freudians, have gone to the original authority to examine their master by such a test as here indicated. Those who do will not find a Galileo; they will meet with the method and manner of the schoolmen.

Freud takes association as the master key, and with this assumption, so absurdly inadequate in view of the searching analysis and the rigorous proof demanded by science, he builds up his system. I say nothing at present as to his great sex idea, his exposition of memory and of dreams, except to remark that I will later bring to demonstration that

* The exposition of these fundamental processes forms the backbone of *Psychology: A New System*, in which, by methods of rigour such as, I venture to say, had never before been introduced into these studies, I showed that these fundamental processes were both necessary and sufficient to cover the whole field of thought. This book has been sold out, but another and better exposition, *Principles of Psychology*, will appear in January.

his reasoning in these questions is unscientific and that certain of his conclusions are ridiculous. I wish to concentrate on that point of his meagre offering of analysis, for, to put an analogy, if a man explained the steam engine by saying that nothing had to be considered but latent heat, he would not only have talked nonsense about the steam engine, but he would have given a false notion of latent heat.

Froude has given us a false theory of mental process, and on his bright particular star of association he has talked moonshine.—I am, etc.,

London, N.W., Oct. 16th.

ARTHUR LYNCH.

SIR,—I wish to comment on one of the numerous misconceptions to which Sir Clifford Allbutt has subscribed in his latest attack on psycho-analysis (in an address which Dr. McBride finds "admirable, scholarly, and scientific"). He identifies the practice of psycho-analysis with that of the confessional (as does also Dr. McBride in his letter), and states that it has been known for centuries in the (Catholic) Church.

Now the most elementary acquaintance with psycho-analysis will inform one that it is concerned with processes of which the subject is entirely unaware, with what is called the unconscious mind, so that, as priests obviously deal only with conscious processes, they are concerned with a completely different sphere. This fact alone, apart from other fundamental differences, would serve to distinguish the practice of psycho-analysis from that of the confessional; in fact I know of no feature common to the two beyond the professional secrecy enjoined in both.—I am, etc.,

DOUGLAS BRYAN,
Honorary Secretary of the
British Psycho-Analytical Society.

London, W., Oct. 16th.

ANIMAL EXPERIMENTS.

SIR,—I was not a little amused by your editorial note on "Animal Experiments in 1921" in your issue for August 26th, 1922.

The law under which these experiments were done I presume is the law advocated by the antivivisectionists, such as Mr. Coleridge and Dr. Hadwen. The reason for my amusement is the statement that "the law demands that the operation shall be performed *antisepically* so that the healing of wounds shall, as far as possible, take place without pain." (Italics my own.)

Now Messrs. Coleridge, Hadwen, and their friends deny the germ theory *in toto* and also deny the value of antiseptics. They ridicule all such precautions.

What a tribute their law pays to the value of antiseptics as a means of preventing pain and facilitating healing! I admire their unconscious advocacy of antiseptics and wonder what has become of their consistency.—I am, etc.,

W. W. KEEN,
Emeritus Professor of Surgery, Jefferson
Medical College, Philadelphia.
1520, Spruce Street, Philadelphia, Sept. 25th.

THE TREATMENT OF ECLAMPSIA.

SIR,—I was sorry I was unable to be present at and to take part in the discussion at Glasgow on the above as I wished, for I must confess it would have pleased me to learn that all is not well with the toxæmia hypothesis of eclampsia. In March of this year in your columns I read that "the toxæmic origin of eclampsia is now accepted." In your issue of to-day we learn that this hypothesis "is not entirely free from difficulties." This, I think, is very satisfactory, because, as I have endeavoured to show, the toxæmic hypothesis is untenable.

Pathologists have already spent such an enormous amount of time in the vain search for a specific toxin explaining eclampsia that it is difficult to believe they are on the right track, and not surprising to find it urged that those who have to treat eclampsia can wait no longer for them. There are, however, already several indications before us which indicate the nature and the cause of eclampsia—that it is simply a uræmia produced by the condition of pregnancy. First, I would put the treatment which experience so far has shown to yield the best results; this treatment, plainly, is the treatment for uræmia. Next, I would remind you of the incidence of eclampsia; this is so peculiar that it shows that the disease cannot be due to any peculiarity in the contents of the uterus. And in itself, it indicates very strongly that the pre-eclamptic state and eclampsia are due to a faulty metabolism induced by pressure

risers in the abdomen. This is supported by the discovery that conditions which diminish the pressure in the abdomen of very great assistance in dealing with the disease. The Dublin school urges placing the eclamptic patient in the lateral position, otherwise, they say, she will drown in her own secretions. The importance of the accumulation of mucus in the bronchi and smaller channels is obvious; but it is doubtful whether all this comes from the nose at month. By placing the patient in the lateral position the pressure in the abdomen is much reduced; not only does it afford the best possible condition for the re-establishment of blood flow through the capillaries of affected viscera, but inquiry may possibly show that it so alters the pulmonary circulation as to check or limit pulmonary congestion and oedema. The puncturing of the membranes, allowing escape of liquor amnii, in order to decrease the volume of the uterus was mentioned by Dr. Campbell, and by earlier writers—for example, McChintock—was noticed as a measure which sometimes stops the fits. Such a diminution in uterine volume can only have one effect, and that is to reduce the intra-abdominal pressure. Conversely, we see how it is that in concealed accidental haemorrhage (in which the uterus becomes very large and tense) eclampsia rapidly ensues, and that the ordinary treatment of tightly binding the abdomen is about as bad as it possibly can be. It cannot stop the bleeding; it simply makes the circulatory conditions under which the liver and kidneys labour worse—if the pressure caused by the distending uterus has not clamped their capillaries the treatment does so.

The emptying of the uterus is a very vexed question. The treatment advised is not to interfere unless absolutely necessary; but all the world knows that the termination of the pregnancy is the best possible thing, if it can be done safely and without making the patient worse. It seems to me that it is the participation of the patient in the labour which explains the anomaly. If a patient acutely ill with the pre-eclamptic process has induction of labour practised on her, the straining which necessarily follows and all her movements facilitate the morbid process, and hence we get bad results. That induction should give better results than accouchement forcé is intelligible; in the former the reaction develops slowly; the latter is a much more rapid affair. In this respect the effects of labour must be remembered; in the pre-eclamptic state the activities of (natural) labour are largely responsible for the institution of fits. Such an objection to Caesarean section cannot, of course, apply, because the patient is anaesthetized. But here there are two distinct states to consider. There is the state of the patient who is desperately ill, who already has had many fits, and whose liver and kidneys are very probably already the seat of extensive necrosis; any treatment under such conditions cannot possibly hope to save the patient. But there are cases in which the patient is not so ill, who has had less fits, and whose liver and kidneys presumably are not so diseased, are not perhaps at the moment necrosed, being simply rendered inactive, and who with the relief of pressure may possibly recover. We cannot compare the results of Caesarean section in those two types of case; nor should we condemn the operation because of bad results in the first class of case.

Many successes after Caesarean section for eclampsia have been recorded, and it is plain from the comments reported in your issue that several writers regard the operation favourably for eclampsia. The point is, the operation should not be withheld as a last resource; as a measure for eclampsia it should be employed, it seems to me, not just to deliver the woman but to prevent any possible straining at a period of the morbid process when any increase of pressure within the abdomen may just be the turning point from a possible recovery to an absolutely certain death. If a woman has had one or two fits and becomes conscious between them, as patients often do, she is bound to strain during delivery by ordinary channels unless deeply under an anaesthetic.—I am, etc.,

London, W., Oct. 14th

R. H. PARAMORE, F.R.C.S. Eng.

UNSUSPECTED PREGNANCY.

SIR,—If the confidence of your correspondent in his *ipse dixit* as to the impossibility of a pregnant woman of average size, etc., not suspecting her condition remains unshaken, I wonder if it will survive the shock of reading the following true tale.

When driving past a farmhouse some years ago I was hailed by the farmer's son, who told me that his aunt, who

had come to keep house while his mother was away on holiday, had been taken ill. I found the aunt, a woman 46 years of age, of "average size," sitting in the kitchen and complaining of abdominal pain. As the pain seemed suggestive of labour pains, I asked her if she was pregnant. She said, No, and seemed surprised at the question. I advised her to go to bed. On examination I found the head low down, and about an hour later a full-time male child of "average size" was born, followed shortly by another child, mummified, and apparently of about 7 months' development.

The shy fiancée of the farmer's son, the only other woman about, was my "nurse," and her plight, as affected by the surprising event, obsessed as she was by the delicacy of her own position, was a curious blend of the comic and the pathetic. The mother was a married woman, and had had one child previously, a girl 18 years of age at that time. Husband and wife were delighted at the birth of a son, and had had no idea of the existence of pregnancy, twin or other. "Wind" and "change of life" had been their diagnosis, and they had been supported in this by their medical adviser, whose name I do not think for a moment was Dr. Graham Grant. *Verb. sap.*—I am, etc.,

Maosantfraid, Mont., Oct. 14th.

W. H. LEWIS.

THE RADICAL PREVENTION OF VENEREAL DISEASE.

SIR,—I thought the published reports of the National Council and the Ministry of Health reached limits of insipid irrationality and smug futility; but Mr. Herbert Caiger's letter (*BRITISH MEDICAL JOURNAL*, October 7th, pp. 661-2) soars to even dizzier limits. His solution of the venereal problem is to "circumcise the heart" and inhibit the sexual instinct.

But Mr. Caiger must not be permitted to discredit the fact that disinfectants do disinfect. He can easily prove of course that soldiers issued with little bottles of lotion without instruction got gonorrhoea even though they drank the lotion; that other soldiers who used their calomel ointment as shaving cream got chancres on their genital organs notwithstanding; and that soldiers who threw away their outfits deliberately nevertheless acquired self-inflicted venereal disease (to avoid the firing line); and even that soldiers to whom no outfits were issued were not protected by the disinfectants they did not get; but what Mr. Caiger cannot disprove is:

1. That without an issue of disinfectants the New Zealand Division had in 1917 an average of 1,000 venereal disease soldier patients.
2. That when in 1918 the issue of disinfectants was made fairly efficient (it was never complete) the New Zealand Division had less than 500 venereal disease soldier patients, a saving of about 4,000 or 5,000 soldiers for the war.
3. That when in 1919, the issue of disinfectants and the prophylactic lectures were stopped, the New Zealand Division again had to maintain over 1,000 venereal disease soldier patients.

As to his question, "Will the failures be less in civil life?" Of course they will. In civil life venereal disease is never a benefit, and always a loss of time and money. For the civilian the choice often is: Keep clean and keep your job. For the soldier: Keep clean—and be shot!—I am, etc.,

London, W., Oct. 12th.

ERNE A. ROUT.

CARDIOLOGY.

WE have received from our reviewer the following note on Dr. Harrington Sainsbury's letter published in the *JOURNAL* last week, p. 703:

"It is not denied that changes in pressure within the right auricle and contiguous veins are associated with, and cause, variations in volume. It does not follow, however, that tracings which record changes in volume are necessarily correct graphs of pressure. The blood pressure in the carotid artery (the artery covered by the receiver) is many times greater than that in the jugular, yet the movement of the recording lever, wave 'c,' produced by the arterial pulse, may be insignificant in comparison with that caused by the jugular pulse. In discussing the wave 'c' Dr. Sainsbury stresses the point that 'the force which generates it is by far the most powerful of the forces operating at the root of the neck and appearing as pulsations. Its waves therefore should be the most pronounced of the three.' They should, if the polygraph recorded the forces which produced pulsations or the degree of pressure in the vessels covered by the receiver; but it does not."

Obituary.

EDWARD COLLETT HORT, B.Sc. PARIS, F.R.C.P. EDIN.

WITH the premature death of Dr. E. C. Hort on the morning of October 15th at Cannes, after a long and trying illness, a man of exceptional ability and charming personality has passed beyond the veil. He was remarkable for originality, not without a touch of genius, for his independence, and for the amount of work that he accomplished within a comparatively short period.

Edward Collett Hort was born in 1868, the third son of the Rev. F. J. A. Hort (1828-92), Hulsean Professor of Divinity in the University of Cambridge, who was described as the "greatest English theologian of the nineteenth century." His elder brother, Sir Arthur Hort, sixth baronet, was until lately an assistant master at Harrow; a younger brother is a member of the profession. Educated at Sherborne and at Emmanuel (his father's) College, Cambridge, Edward Hort finished his medical education at Guy's Hospital, obtaining a medical qualification (L.S.A.) in 1896 and marrying in the same year. The next ten years or so were spent in various parts of the world, some in America, where he had many adventures, but eventually he settled down to ordinary medical work in the south of France. About 1907 he came back to England and bought a 'practice' at Torquay; his outlook on life now appears to have undergone a change, for he became a keen laboratory worker. Hort, indeed, was one of those who develop late in life, being nearly 40 when he started on the work which he henceforth pursued with ceaseless, almost feverish, energy in spite of the handicaps of bad health and the necessity of supporting his family by general practice. While at Torquay observation of a patient with a haemorrhagic form of disease attracted his attention to the use of horse serum and led to the appearance of his first published papers—namely, on its use in gastric and duodenal haemorrhage (1907, 1908), based on the hypothesis that the ulceration was the outcome of autolysis due to proteolytic bodies in the blood, and that this process could be counteracted by the administration of horse serum. After about a year he migrated to Harley Street, and at once became busily engaged in a high-class practice. For a time he was assistant physician to the Italian Hospital, but his mind was now actively evolving problems in connexion with bacteriology and serology, and every spare moment was devoted to research work, which was carried out first in Sir Lenthal Cheate's private laboratory at King's College and then at the Lister Institute. A grateful patient supplied an endowment, and this Constance Trotter Fund enabled him to enlist the help of skilled collaborators. A constant stream of papers now began to appear—for example, in the *Journal of Hygiene* (several in collaboration with Dr. W. J. Penfold); the *Quarterly Journal of Medicine* (1911), the *Proceedings of the Royal Society* (1910, 1912), the *Journal of Vaccine Therapy*, the *Proceedings of the Royal Society of Medicine*, the *Journal of the Royal Army Medical Corps*, the *Lancet*, and our columns—on various aspects of bacteriology, such as micro-organisms and their relation to fever, experimental fever, salvarsan fever, vaccines and fever, autotoxaemia and infection, and the autitryptic index.

Early in 1914 he investigated the bacteriology of typhus fever with Dr. W. W. Ingram and described a filter-passing organism, infective to monkeys, which was pleomorphic, presenting a coccobacillary form as a harmless phase. This was the first of a series of papers which came out during the war, advocating the recognition of pleomorphism or a complex life cycle for bacteria. Among these were four on cerebro-spinal fever, embodying the results of work done while honorary physician and director of the bacteriological staff of the Addington Park War Hospital (1914-18) in collaboration with Drs. C. E. Lakin and T. H. C. Benians and later with Captain A. H. Canfield, C.A.M.C. He contended that the meningococcus is not the cause of the disease but merely a late non-infective phase in the life history of an organism allied to the *Ascomycetes* and infective only in its earlier phases; this conclusion involved him in a controversy with Mr. J. Ramsbottom, mycologist to the British Museum, and his advocacy of the complex life cycle of the bacteria did not gain any acceptance, and indeed very little notice, from other bacteriologists except for a generous plea for recognition from Professor J. G. Adami (*British Medical Journal*, 1916, ii, 525). Whether or not Hort's revolutionary conception may eventually prove to be correct, there is no doubt of the enormous care that he devoted to avoid the

obvious fallacies of contamination, and that his enthusiasm and ingenuity command admiration. His paper, entitled "The meningococcus of Weichsolbaum," appeared in the *British Medical Journal*, 1917, ii, 377, and was illustrated with drawings to show his conception of the development of "giant meningococcus."

While at the Addington Park War Hospital he contracted dysentery and was extremely ill; from this he slowly recovered and, after serving as temporary lieutenant-colonel in charge of a convalescent hospital on the Riviera, turned his energies into another direction, the invention of suitable foods for the starving Russians, as an interlude to the bacteriological work which it was his ambition to see overwhelmingly proved and accepted. But this was not to be; last year symptoms of visceral tuberculosis became urgent and the disease slowly gained on him.

With his most active and energetic nature it was not surprising that Hort had other interests besides bacteriology and that he was a skilled musician and a keen fisherman. His special charm of manner and lovable disposition brought him friends wherever he went. He leaves a devoted wife and two daughters, the elder of whom had assisted him in his work.

We are indebted to Dr. J. G. ADAMI, F.R.S., Vice-Chancellor of the University of Liverpool, for the following appreciation of Hort and his work in bacteriology:

It is as easy to criticize and damn with faint praise men of the type of my old friend E. C. Hort as it is difficult to give a just appreciation of their sterling virtues. For in truth he was a genius, and geniuses are difficult to live with, not easy to guide, and have a way of "kicking over the traces" that is disconcerting to ordinary mortals. Particularly is this so when they have Irish blood in their veins. What is more, he was an example of the man who develops late and in an unacademic manner. I knew him as an undergraduate at Cambridge in the late eighties or early nineties—frank, cheery, and irresponsible. The contrast between him and his most studious father, the scholarly colleague of Professor Westcott, was most striking. The last accusation one would have made was that he was either given to hard work or scholarly. And the air of boyish irresponsibility clung to him throughout life. Nor so far as I can learn was his career as a medical student in any way distinguished. If I am not mistaken, the death of his father rendered it necessary that he should qualify without delay. Leaving Cambridge he entered at Guy's and obtained the L.S.A. in 1896. I lost touch with him for some years until from 1908 onwards there came pouring out a series of papers upon serology and immunization that showed the presence among us of a man of pronounced originality, an observer of phenomena passed over by most of us. Who, for example, but Hort would have investigated the pyrogenic effects of (presumably) pure distilled water? All of us who had been interested in the bacteriology of cerebrospinal fever had observed irregular forms of the meningococcus; we, however, had focussed our attention upon the detection of the normal forms: Hort by preference concerned himself upon the abnormal and interested himself in them as throwing light upon the life-cycle of the organism.

What had happened? More to this, that engaged in ordinary practice he had become interested in immunology—so interested that notwithstanding the very partial training he had received in bacteriological technique he determined to test the phenomena for himself. Gifted with a natural love for experiment, and with a manual dexterity much above the ordinary, he established a laboratory in his own house, and with little help from outside, in the shape of routine training in recognized laboratories, he worked at problem after problem. Doubtless he learned much from the well-trained co-workers when in the latter years he attached them to himself. But working incessantly and with intense enthusiasm he elaborated a technique that was remarkable. I shall not easily forget the revelation of methods, as precise as they were original, that he gave in 1918 when a committee appointed by Sir Alfred Keogh, and consisting of Sir William Leishman, Colonel Harvey, and myself, visited his laboratory in order that he might demonstrate to us his work upon the pleomorphism of the typhoid bacillus which he had reported to the War Office. We might differ from him as to the interpretation to be given to his facts, but the facts were there before our eyes—the growth and multiplication of the typhoid bacilli at a certain stage and under certain conditions by processes other than those of simple binary division.

In short, as one who was not a product of the schools, he saw bacteriological phenomena from an independent angle, and as a consequence he obtained novel results of the first importance. It is quite natural that men of his type are misunderstood, that the ordinary bacteriologist brought up to employ the routine methods should mistrust the findings of one who has no credentials of work performed under accepted leaders in well known laboratories. It is true also that as a self-taught man his training was imperfect; with deep knowledge of some parts of his subject he was poorly grounded in collateral branches of science. His knowledge of protistology, for example, was incomplete. Nor as an independent worker did he possess that body of colleagues in different branches of science to whom to turn for advice and assistance in the explanation of his facts. It is the results obtained, and not necessarily his interpretation of them, that in my opinion must be accepted and must revolutionize our views as to the life-history and properties of the bacteria. I am convinced that future years will establish Hort as one of the masters in bacteriology.

DR. PRATUL KUMAR GHOSH, of Treeton, near Sheffield, who died on October 1st at the age of 41 years, was the son of a well-known Hindu medical practitioner of Calcutta and Dacca. Educated at Dacca College and the Universities of Calcutta and Edinburgh, at the beginning of the war Dr. Ghosh joined the Indian Ambulance Corps, and served for nine months at the York Place General Hospital, Brighton. Returning to Edinburgh he graduated M.B., Ch.B. in 1915, and, after acting as an assistant, in 1919 he acquired a practice at Treeton and Woodhouse, near Sheffield. Here Dr. Ghosh soon endeared himself to his patients by his devotion to their interests and at the same time gained the goodwill of all his fellow practitioners in the neighbourhood by his loyalty to professional ideals. His death from pneumonia on the eve of a well-earned holiday was the result of several years of overwork in a heavy industrial practice. Dr. Ghosh was a member of the Rotherham Division of the British Medical Association, and was also a popular member of the Roushaw Park Golf Club. He was surgeon to the Rotherham collieries and acted as one of the medical referees for the Yorkshire Coal Owners Indemnity Company and several life assurance companies. His remains were cremated at Sheffield on October 3rd. He leaves a widow and one child, with whom all classes in the district deeply sympathize.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

At a congregation held on October 13th it was resolved to confer upon Professor H. R. Dunn, D.M.Oxon., newly appointed to the chair of pathology, the complete degree of M.A. *honoris causa*. Professor Dunn has since been elected to a professorial fellowship at Trinity Hall.

The following medical degrees were conferred:

M.D.—F. G. Lescuyer.

M.B.—H. L. Wiley.

M.B., B.Ch.—C. S. Atkin, A. E. Roche.

The following have been approved in Part II (Pharmacology and General Pathology) of the Second M.B. Examination, October, 1922:

B. E. Ahrens, E. L. Auguste, G. W. Bamber, C. M. Barker, W. A. Barnes, C. O. Beane, I. C. P. Beauchamp, S. A. Beishaw, W. A. Bourne, C. V. Brook, G. H. Brown, C. B. Buckley, R. C. L'E. Burges, R. W. Butler, A. Carnegie Brown, A. N. Carruthers, W. E. Chiesman, J. B. Church, W. R. F. Collis, C. K. Colwill, W. F. Cooper, W. S. C. Copeman, R. W. Cunningham, R. Cunningham, R. S. Dewey, M. S. Dehurst, J. Dockray, C. E. Donaldson, R. W. B. Ellis, T. I. Evans, T. F. Everett, E. O. Fox, J. H. Gibbons, H. E. Goodby, F. Goldby, E. P. Gough, B. Graves, R. A. P. Gray, E. J. Greenwood, H. F. Griffiths, J. L. Groom, J. Grosch, K. H. A. Gross, W. S. Grove, R. F. Guymer, H. J. Heatheote, A. C. de B. Helme, J. D. Hindley-Smith, J. C. Hoag, A. T. Howell, J. T. Irving, D. McI. Johnson, W. E. Joseph, J. J. Keevil, L. A. Key, M. E. Lampard, W. E. B. Lloyd, T. F. McNair Scott, J. P. Marsden, F. Martin, R. D. Milford, J. G. Milner, V. S. Mitcson, E. D. Moir, E. G. Morris, J. D. R. Murray, H. P. Nelson, C. P. Newman, H. W. Nicholson, G. F. Oakden, C. L. Owen, J. J. Panting, R. W. L. Pearson, H. C. Pierce, C. G. E. Pimbleston, J. D. Procter, P. E. Pyra, J. H. Randall, A. M. Rhydderch, J. W. W. Robertson, R. P. Ross, G. L. F. Rowell, T. W. E. Roeden, H. W. Seidler, K. G. Salmon, H. B. Savage, S. W. Sav-
R. E. Smith, W. Smith, W. E. Ba-
B. C. Tate, G. K. Taylor, E. J. E.
J. G. E. Vachell, I. L. Warner,
Wimbush, R. M. Winderley, L. I.
Wyne-Edwards.

The plan for the December examinations for medical and surgical degrees has now been published. The first M.B. examination and Part I of the second M.B. examination will begin on December 21st, Part I of the third M.B. on December 12th, and Part II of the third

DR. F. L. THOMAS, honorary medical officer and ophthalmic surgeon to the North Devon Infirmary, has been elected mayor of Barnstaple.

FOUR lectures in physic will be delivered at Gresham College, Basinghall Street, E.C.2, on "The brain and mind: moral responsibility, criminal responsibility," by Sir Robert Armstrong-Jones, C.B.E., M.D., on Tuesday, Wednesday, Thursday, and Friday, October 24th, 25th, 26th, and 27th, at 6 p.m. Admission to the lectures is free.

A MEETING of the Society of Superintendents of Tuberculosis Institutions will be held at 122, Harley Street, W.1, on Friday, October 27th, at 4 p.m., when papers will be read by Sir Robert Jones on tuberculous disease of the knee, ankle and tarsus, and by Dr. Gordon Pugh on the treatment of tuberculous disease of the spine and hip-joint. There will also be a discussion on the curriculum for the training of nurses in tuberculosis.

THE formal opening of Langham Tower as the Sunderland Training College for Women Teachers took place on October 6th, in the presence of a large company, when Alderman Dr. R. Gordon Bell, chairman of the Sunderland Higher Education Subcommittee, declared the new premises open. On behalf of the staff and students, the Principal of the College presented to Dr. Gordon Bell the academic robes of his doctorate in medicine of Glasgow University. The Principal asked him to accept the gift as a memento of the occasion, and of their gratitude for the work he had done for higher education and in particular for the Training College.

THE number of undergraduates in residence at Oxford this term and the number of freshmen are both slightly lower than this time last year. The number of freshmen this year is 1,043, as compared with 1,073 in Michaelmas term 1921, and the total number of undergraduates is 3,687, compared with 3,928 last year. The number of new women students shows an increase from 225 last year to 263 this year; the total also is larger—722 as compared with 628.

THE second Winter School for Health Visitors organized by the Women Sanitary Inspectors' and Health Visitors' Association will be held in London from December 28th to January 11th. Lectures on various aspects of public health work will be given. Particulars may be obtained from the Secretary, Miss C. Macdonald, 5, York Buildings, Adelphi, W.C.2, on receipt of a stamped addressed envelope.

WE deeply regret to announce, as we go to press, the death, on October 18th, of Sir JAMES GALLOWAY, K.B.E., C.B., Senior Physician to Charing Cross Hospital. An obituary notice will appear in our next issue.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

ATTORNEYS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Attilogv, Westrand, London*; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630, Gerrard.

3. SECRETARY of the British Medical Association, *Edinburgh*; telephone, 4301, Central.
4. SECRETARY of the British Medical Association, *Edinburgh*; telephone, 4301, Central.

QUERIES AND ANSWERS.

INCOME TAX.

"G. H. S." has been refused an allowance for the cost of replacing a car on the ground that his replacements have been unnecessarily frequent.

* * This ground seems quite insufficient. "G. H. S." is in general practice, and is therefore assessed under Schedule D. He is entitled under the rules of that Schedule to deduct expenses incurred professionally whether necessary or not—that point applies only to assessments under Schedule E in respect of the remuneration of employment—for example, of a salary. Apart from

this the objection taken is unfair, seeing that the more frequent the replacement the less, other things remaining the same, each individual replacement will cost. We suggest that the local inspector be asked to quote his legal authority for the refusal.

"H. S. B." has been refused deductions on account of expenses incurred in connexion with (1) Medical Defence Union, (2) a medical institute, (3) British Medical Association, (4) post-graduate course, (5) legal arrangements for partnership.

* * (1), (2), and (3) are allowable, or at least in the ratio in which the total subscriptions of each body for the year were actually expended on current work. (4) Not allowable—represents capital outlay. (5) Not allowable—it is an expense incurred in acquiring the partnership share and is therefore of a capital nature.

"NOVICE" has recently purchased a half-share of a practice.

* * 1. The assessment must be made on the amount of the earnings of the practice as a whole, and in dividing the duty payable between the partners no regard should be had to the fact that the cash receipts are not equally divided because portions relate to periods prior to the partnership. The cash receipts are taken as forming the basis for the calculation of the assessment for the current year, and it is on the earnings of that year that tax is being paid.

2. "Novice" can deduct tax at the standard rate from the payments of interest—for example, instead of paying £10 gross he should pay £10 less tax at 5s. in the £—that is, £7 10s.

3. On the facts stated no other deduction appears to be due.

"A. M. F." is being assessed to income tax in respect of untaxed interest received in the previous year, though the war loan stock has been so dealt with as to yield taxed instead of untaxed interest.

* * If "A. M. F." has now no income in the form of untaxed income he would not seem to be assessable. If he has received untaxed interest—even to a small amount—in this financial year he would be assessable on the amount of interest received in the previous year. Our correspondent will probably find that he did not pay tax for the first year he received the interest as it was not assessable until the second year.

SWEATING IN PULMONARY TUBERCULOSIS.

"IRISHMAN" asks for advice in the treatment of very profuse sweating in a case of pulmonary tuberculosis; the patient is 32; the area of lung involved is quite moderate, as also are the evening temperature and the amount of sputum; the hygienic conditions are superb, and two nurses are in attendance; the routine remedies are futile, and there is a definite history of hyperidrosis in the family; the only treatment for the tuberculosis followed is that of "nascent iodine."

LETTERS, NOTES, ETC.

TRICHINIASIS.

Drs. D. A. RICE and H. O. WILLIAMS (Milford Haven) write: In your issue of April 29th, 1922 (p. 630), you were good enough to allow us to describe certain symptoms occurring in a group of cases under our care. Judging by the correspondence we received our note was not without interest to many of your readers, and we shall be glad if you will allow us to state that the symptoms were those of trichiniasis, and not, as suggested, of an abdominal form of influenza. A full report of the outbreak appeared in last week's *Lancet*.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 38, 39, and 40 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 36, 37, and 38.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 147.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£ s. d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Order must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so

delivered, addressed to the Manager, 429, Strand, London, on the first post on Tuesday morning if not paid for at the time, should be

sent to the Post Office to receive postal notes in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

191. Chronic Intestinal Dyspepsia in Children.

A. BROWN, A. M. COURTNEY, and I. F. MACLACHLAN (*Brit. Journ. Child. Dis.*, July-September, 1922, p. 113) record the results of their investigations at the Nutritional Research Laboratories of the Hospital for Sick Children and the Department of Pediatrics of the University of Toronto. Their cases were divided into three groups—namely, (1) mild, (2) moderately severe, and (3) severe, this last group representing the classical type of chronic intestinal indigestion or intestinal infantilism of Herter. In the first group there were four cases, ranging in age from 2 to 5 years. The chief symptoms, which had been present for from four months to about a year before coming under observation, consisted of looseness of the bowels, with definite evidence of fermentation, general lack of tone, and fatigue with restless sleep. A mild degree of anaemia was present. There was a record of excessive feeding with breadstuffs and sweets. A response to moderate high protein diet with lactic acid milk took place in about six to nine months' time. In the second group, in which there were six cases, ranging in age from 18 months to 5 years, the symptoms of carbohydrate indigestion were exaggerated. There was pronounced evidence of under-nutrition with distension, so that a more rigid exclusion of carbohydrates from the diet was required, and recovery took place from six months to a year longer. The third group, in which there were nine cases, presented the classical picture of varying degrees of emaciation with greatly distended abdomen, lack of growth, physical and mental fatigue, and a moderate degree of anaemia. The previous histories of these patients consisted of repeated digestive upsets, usually associated with diarrhoea and invariably connected with a high carbohydrate diet. Treatment consisted in keeping these patients on an exclusively protein diet until the stools showed no evidence of fermentation and lost their acid reaction. Carbohydrate foods were then added gradually until a fuller diet was reached. The writers maintain that the outstanding feature in chronic intestinal indigestion is fat intolerance. As this cannot be overcome in the presence of excessive fermentation such as exists in all cases of chronic intestinal indigestion a diet was selected to reduce the process of fermentation to a minimum, consisting of protein or lactic acid milk, curds, meat, cheese, and gelatin. This method was employed in seven cases, in all of which a satisfactory recovery took place. Tables are given showing the results of metabolic investigations in three cases.

192. The Medical Applications of Diathermy.

ME GRUNSPAR DE BRANCAS (*Journ. de radiol. et d'électrol.*, August, 1922, p. 364) states that the chief physiological effects of diathermy are three in number: it is a powerful sedative of pain, it produces hyperaemia, and it increases secretion. The indications for its use are therefore numerous. The writer has employed it with success in the treatment of old pleurisy, neuralgia, and peripheral neuritis, and most of all in arthritis. Gonorrhoeal rheumatism is rapidly relieved when treated from its onset by diathermy. Gouty arthritis is also greatly benefited by it. Special mention should be made of the application of diathermy to gynaecological affections. Numerous cases of perimetritis and parametritis and chronic neuralgia of the adnexa, due to various causes, have been improved and cured by diathermy after many other methods have been tried in vain. Lastly, gastralgia, dyspepsia, and spasm of the pylorus have been treated by diathermy with encouraging results. According to Aymard it has also been used with benefit in some painful inflammatory affections of the gall bladder.

193. The Value of Quinidine in Auricular Fibrillation.

A. E. CLARK-KENNEDY (*Quart. Journ. of Med.*, July, 1922, vol. xv, No. 60, p. 279) records the results of careful observations on the value of quinidine in the treatment of 20 cases of auricular fibrillation. He gives notes of the cases and adds a review of the present position of our knowledge of the action of quinidine in auricular fibrillation, with theoretical considerations. Space limits permit only a few of his results to be mentioned. Twenty unselected cases of auricular fibrillation admitted to the medical wards of a general hospital were treated with quinidine and in 17 (85 per cent.) normal cardiac rhythm returned. Of these 17 successful cases 12 were rheumatic, 1 rheumatic and infective, 2 degenerative, and 2 had

auricular fibrillation associated with exophthalmic goitre. Of the 3 unsuccessful cases 2 were rheumatic and 1 degenerative. In all cases quinidine was pushed to the maximum dose that it was thought safe to administer. In 3 of the 17 successful cases relapses occurred prior to their discharge from hospital, but in 14 the normal rhythm persisted until the patient was discharged. Mitral stenosis was present in 1 of the 17 cases in which the normal rhythm was restored. As regards the ill effects of the drug, certain toxic symptoms were common—mild gastric symptoms, nausea, anorexia, vomiting, abdominal pain, diarrhoea, headache; but in most cases these symptoms passed off spontaneously, though the drug was continued in the same dose. Embolism occurred in 3 cases, and probably in 2 others. In one case small doses of quinidine led to excessive vomiting, and a later severe syncope attack occurred. As quinidine is known to cause amblyopia, visual symptoms of moderate severity are an absolute contraindication to continuing the drug. The author thinks it is logical to administer quinidine also as prophylactic to patients suffering from auricular fibrillation of the paroxysmal type, and also possibly to patients the victims of mitral stenosis and exophthalmic goitre, seeing that auricular fibrillation is so common in these cases.

194. Differential Diagnosis of Encephalitis, Poliomyelitis, Botulism, etc.

G. E. EBRIGHT (*Amer. Journ. Med. Sci.*, August, 1922, p. 25) discusses the differential diagnosis of epidemic encephalitis, acute poliomyelitis, botulism, and certain forms of food and drug poisoning, such as poisoning by veronal and the belladonna group, which may affect the cranial nerves and cause diagnostic difficulties. A feature of epidemic encephalitis is the spread-out course of the symptoms, in sharp contrast to poliomyelitis, in which the total extent of the paralysis may occur within a few hours, or at most a few days. Somnolence, asthenia, irregular fever, and cranial nerve palsies are suspicious symptoms of epidemic encephalitis, especially if the condition has been preceded by "influenza." In mild cases the somnolence may not be very marked, but as a rule, lethargy distinguishes the mental condition from that of poliomyelitis or botulism, in which the mind usually remains clear, though in poliomyelitis drowsiness may be present, from which, however, the patient can be easily roused, and is then irritable. Meningeal invasion in poliomyelitis is characterized by neck stiffness and weakness of the anterior neck muscles, drowsiness, hyperaesthesia, ataxic gait, and sometimes muscle twitching. Cases of botulism are characterized by double vision, weakness, and difficulty in walking, inhibition of secretions, dysphagia, aphonia, and constipation, and the condition may be confused with acute poliomyelitis, but an absence of prodromal symptoms and fever, together with the fact that in poliomyelitis definite paralysis of groups of muscles in the extremities generally occur, are diagnostic features. Further, there may be a tendency for the head to fall forward in botulism owing to paralysis of the posterior or all of the muscles of the neck, while in poliomyelitis the head may tend to fall backwards, from stiffness of the posterior neck muscles with weakness of the anterior muscles and movements may be painful. Drugs of the belladonna group inhibit secretions and dilate the pupils, as occur in botulism, but in the former there are cerebral symptoms, flushings, etc. Veronal poisoning may resemble encephalitis with ptosis, double vision, and nystagmus, but without other paralyses, gastro-intestinal disturbance, or diminished secretion. Methyl alcohol poisoning, by its symptoms of dizziness, gastro-intestinal disturbance, optic neuritis often resulting in blindness, and cloudiness of mental functions, may present diagnostic difficulties, but the state of the optic nerve and the mental condition easily distinguish it from botulism and poliomyelitis.

195. Neo-salvarsan in Gangrene of the Lung.

S. T. MADSEN (*Medicinsk Revue*, July and August, 1922, p. 312) has given neo-salvarsan in 5 cases of gangrene of the lung or bronchiectasis. One of these cases, which was complicated by tuberculosis, ended fatally. In the remaining cases considerable success was achieved by the intravenous injection of neo-salvarsan, given at intervals of four to seven days. The dosage of each injection ranged from 0.3 to 0.6 gram, the quantity being rapidly increased in each case. The total quantity of neo-salvarsan given varied from 2.7 to 3.9 grams. The improvement was so uniform and striking in all four

cases that its relationship to the treatment could hardly have been accidental. In one case in which spirochaetes were found before the treatment was instituted none was demonstrable after the third injection. In none of these cases was there any sign of syphilis. The author, who gives details of 13 cases of purulent disease of the lungs and respiratory passages, has also found that restricting the fluid intake to a minimum, according to Singer's system, is often remarkably effective in reducing the purulent expectoration and restoring the patient's general health.

293. The Nervous System in Influenza.

G. C. BOLTON (*Nederl. Tijdschr. v. Geneesk.*, June 10th, 1922, p. 2255) remarks that it is a well-known fact that the central nervous system is very sensitive to the still unknown bacterial cause of influenza or its toxins, as is shown by the numerous cases of lethargic encephalitis, which Bolton regards as influenzal in origin, and influenzal psychoses. Most of the latter are due to bacterial intoxication, and the clinical picture is one of toxic delirium, but in some of the cases there is the possibility of slight monogenic changes and of multiple foci of encephalitis. Bolton also draws attention to numerous symptoms occurring in or directly after an attack of influenza, which indicate damage to the sympathetic, such as fall of blood pressure, loss of hair, cyanosis of the hands and fingers, profuse sweating, acroparasthesia, etc. These phenomena are sometimes very persistent, and can be best explained by the hypothesis of very small foci of encephalitis in the floor of the third ventricle or in the fourth ventricle (vasomotor centre). Von Riese, who first described these symptoms, had very good results from administration of pituitary extract. Bolton generally uses adrenalin or thyroid extract, as these two hormones are the most powerful agents for raising the sympathetic tone. In addition to cases of polycyrcutis and one of transverse dorsal myelitis, Bolton saw three cases of meningitis occurring directly after influenza during the last severe pandemic. They were all fatal, and did not differ in any respect from meningitis of pneumococcal, staphylococcal, or streptococcal origin. Bolton, like many others, has noticed that a mild attack of influenza may be followed by very severe nervous symptoms.

297. Dietetic Treatment of Chronic Arthritis and Its Relationship to the Sugar Tolerance.

A. A. FLETCHER (*Arch. Intern. Med.*, U.S.A., No. 1, vol. 30, July 15th, 1922, p. 106) records the results of dietetic treatment in 100 cases of chronic non-purulent arthritis. Gonorrhoeal cases were excluded, and dietetic treatment was not commenced until at least six weeks after the onset; also the patients were allowed to remain for two weeks in bed until the process appeared to have become more or less stationary. At first various diets were tried. Reduction of the carbohydrates was sometimes followed by much improvement; but better results were obtained by a more general reduction of diet, and in the large majority of the 100 cases the diet consisted of three glasses of milk, three glasses of butter milk, half a grape fruit, and one or two oranges a day for one week; then the gradual addition of eggs, fish, fowl, meat, 5, 10, and 15 per cent. vegetables, fruits, junkets, and jellies; and finally, brown-bread in small amounts. Within four weeks the food value was increased up to 1,500 to 2,000 calories daily. If no improvement occurs in this time generally it is useless to continue the diet. Sugar tolerance tests were also made, and the blood sugar estimated. Of 100 cases of chronic arthritis treated by this reduction of diet alone, 8 recovered and 43 improved quite evidently. The sugar tolerance was decreased in the large majority of those cases. Patients who have a low sugar tolerance are much more frequently benefited by reduction in diet than those cases with a normal tolerance. In certain cases of chronic arthritis, dietetic regulation appears to be the most effective form of treatment. The lowering of the sugar tolerance is a useful clinical indication for this procedure.

SURGERY.

298. Tumours of the Spinal Cord.

C. H. FRAZIER and W. G. SPILLER (*Journ. Amer. Med. Assoc.*, September 23rd, 1922, p. 1024) analyse 14 consecutive cases of spinal cord tumour, and lay emphasis on certain points which are calculated to make for earlier diagnosis in such tumours, and, as a result, to the consideration of surgical treatment before degeneration of the cord has deprived the patient of relief from crippling deformities. In 13 cases out of 14 pain was not only a conspicuous symptom but was the first symptom. While in later stages pain may be referred to a more spread distribution, the original zone of pain continues about the course of the disease, and is, therefore, an

important localizing sign. In one-third of the cases three or more years elapsed between the onset of pain and the first signs of motor impairment. Given a case with pain of definite localization, aggravated by movement, coughing, or sneezing, and persisting with occasional remissions, without variation except in degree, in the original region for months or for longer periods, the authors consider that one should at least have in mind the possibility of a spinal cord tumour. Subjective sensory disturbance—variously described as a sense of numbness in the limbs, itching, tingling, or a sense of constriction about the limb or trunk—was invariably the second symptom. In not one of the series was there a typical Brown-Séquard syndrome. Motor disturbances were present in each of the 14 cases in greater or less degree. Too much stress, the authors consider, must not be laid on the presence of a spinal block—it is a late rather than an early symptom. Xanthochromia was present in only 5 cases, and these were of long duration. In the accurate localization of a tumour the following points were found of the greatest assistance: (1) level of sensory loss or impairment; (2) point of referred pain; (3) sympathetic phenomena; (4) absent reflex; (5) muscular atrophy. The exposure and removal of tumours of the spinal cord present rather elementary surgical problems, but the authors found that when mistakes were made in the attempt to expose the tumour the opening in the spinal cord was invariably too low. To avoid this error the following rule is recommended: The level of the lowest lamina to be removed should correspond with the position of the segment representing the highest level of sensory loss. As endotheliomas grow from the spinal meninges, the operator should remove, with the tumour, that portion of the meninges from which it originated, to prevent recurrence.

299. Diagnosis and Treatment of Choked (Optic) Disc.

V. HIPPEL (*Klinische Wochenschrift*, June 3rd, 1922) distinguishes between "choked disc," papillitis, and optic neuritis, and mentions various views held as to the causation, since von Graefe first showed that "choked disc" was frequently associated with brain tumour, and usually with increased intracranial pressure. At the early stage uncomplicated "choked disc" does not cause disturbance of vision (in contrast with the majority of cases of papillitis), but "choked disc" of sufficiently long duration may lead to permanent blindness. "Choked disc" usually indicates increased intracranial pressure. "Choked disc," if not treated, or if treated only with iodides and mercury, is followed in the great majority of cases by incurable blindness, but by correct and early treatment usually this can be avoided. Horsley showed that not only removal of the diseased cerebral foci, but also simple trephining, with opening of the dura mater, causes the subsidence of the "choked disc" in the majority of cases. When the diseased foci cannot be removed operative treatment for the relief of the "choked disc" should be undertaken. Lumbar puncture is not advisable if cerebral tumour is probable; but in syphilitic cases and in meningitis permanent good results may be obtained by this treatment. Palliative or decompression trephining (subtemporal on the right side) is a relatively simple operation and can be performed under local anaesthesia. The prospect of curing "choked disc" without loss of vision is only good when the operation is undertaken early, before vision has commenced to fall. The author concludes from experience in 58 cases that recovery, without disturbance of function, can be obtained in the majority of cases of "choked disc" by early surgical treatment; and though the majority of the patients die of the primary disease in the course of a few years they do not usually lose their sight. A minority of the cases are permanently cured, and thus, if recovery occurs from the primary disease, blindness (otherwise so frequent) is avoided.

300. Results of Tonsillectomy.

F. NORSK (*Hospitaltidende*, July 12th, 1922, p. 62) has investigated the after-effects of tonsillectomy in patients operated on between 1910 and 1919. Questionnaires were addressed to these patients, of whom 130 answered in writing and 72 presented themselves for re-examination. Of the 102 operated on for frequent attacks of acute tonsillitis, 85 were symptom-free, 9 were better, and 8 still suffered from symptoms. Of the 33 operated on for peritonsillar abscess, 30 were symptom-free, 2 were better, and only 1 was not improved. All of the 14 patients operated on for acute tonsillitis in conjunction with rheumatic fever proved to be symptom-free. The remainder of the cases in which tonsillectomy was performed represented an assortment of diseases, including recurrent attacks of diphtheria and malignant disease. The author concludes that tonsillectomy achieves a complete cure in 94 per cent. of cases of peritonsillar abscess, provided the upper pole of the tonsil is entirely removed. The percentage of cures by tonsillectomy in retarding acute tonsillitis is 84. In as great a proportion as 24 per cent. he found remains of tonsillar tissue, but it was not clear whether this tissue

had been left at the time of the operation or represented extension of the lingual tonsil to the tonsillar fossae. Commenting on this investigation, H. MYGIND (*Ibid.*) states that he never performs tonsillectomy on professional singers unless the indications are urgent, for there is no guarantee that the operation will not be followed by adhesions about the palatine arches, spoiling the singer's voice. He has often observed professional singers with good voices and yet with considerable hyperplasia of the tonsils, yet in no respect did this condition affect the voice.

301. Results of Treatment of Congenital Dislocation of the Hip.

H. A. T. FAIRBANK (*Brit. Journ. of Surgery*, July, 1922, p. 24) arrives at the following conclusions: If cases are sent to the surgeon before the end of the third year an anatomical cure ought to be obtained by manipulative reduction in about 75 per cent. of the unilateral cases and 50 per cent. of the bilateral. In the majority the function should be excellent for many years. The treatment adopted has been the Lorenz method with slight modifications. Open reduction should not be necessary in the younger cases, but may be useful where manipulative reduction is impossible. This operation should only be performed in selected cases after 6 years of age. The following complications during and after reduction may be met with: fracture of the femur, changes in the head of the femur similar to pseudo-coxalgia, and arthritis as shown by stiffness in the hip. Anterior displacement of the head of the femur is not a rare complication and usually occurs while the child is in the plaster case. When this occurs it should be corrected without delay. Traumatic and late redislocations are not common. Apart from trauma, the cases have probably been imperfect from the first. After reduction the leg should be put up in full right-angled abduction in plaster and retained in this position for never less than six months. Patients are encouraged to walk after the first month in plaster. The brace is not included in the plaster as a routine. After six months, massage and exercises should be carried out for some months. This probably exerts a permanent influence on the function of the hip, but is not likely to affect the anatomical result.

302. Retroperitoneal Rupture of the Duodenum.

W. H. HARRIS (*Canadian Practitioner*, July, 1922, p. 294) discusses retroperitoneal rupture of the duodenum and gives notes of two cases together with a review of the literature. Arising from violence by blunt force, leaving very little visual evidence of abdominal injury, the lesion usually occurs in the descending or transverse duodenum, where there is no true mesentery, the fixed duodenum being crushed against the lumbar spine. Since a fundamental difference between extra- and intra-peritoneal ruptures is that in the latter symptoms arise earlier and are more pronounced, retroperitoneal duodenal injury may be suspected when the symptoms of suppurative effusion following an upper abdominal blow are delayed in onset, and, apart from this, the signs of intra- and extra-peritoneal bowel rupture are very similar. In diagnosis chest injuries, signs of which are often referred to the abdomen, must be excluded, the symptoms of bowel rupture from injury being pain, tenderness, and rigidity (less marked than that characteristic of ruptured duodenum) and liver dullness, with the general symptoms of shock. The transmission of cardiac and respiratory sounds over the abdomen sometimes occurs as a symptom of gas infiltration of the peritoneum, and post-cervical pain on pressure over the abdominal wall, owing to diaphragmatic irritation of the phrenic nerve distributions, may be elicited. At operation the most valuable sign pointing to the seat of the lesion is a sense of crepitation due to retroperitoneal emphysema, which, at first most marked in the region of the transverse mesocolon, spreads downwards over the right kidney, into the root of the mesentery, and even into the pelvis or upwards into the mediastinum. Extravasation of blood and duodenal contents always occurs, with delayed symptoms localized to the right upper quadrant, and the absorption of toxic material from this effusion is an important factor in the high mortality of these cases. Success in treatment depends upon early operation by suturing the severed ends and performing a gastro-enterostomy, but owing to the grave condition of the patient a simple drainage is sometimes all that should be attempted.

303. Resection of the Elbow-joint.

MOCQUOT (*Bull. et Mém. Soc. Chir. de Paris*, May 16th, 1922) reports the case of a female patient with bilateral ankylosis of the elbow-joints. He performed resection of the right elbow-joint, with the placing of a graft of fascia lata in the joint. The two elbows were ankylosed at an angle of about 140 degrees; this condition dated back for six years, being

the result of a gonococcal infection. It was a crippling condition, and it was only with difficulty that the patient could raise a spoon to her mouth with the left hand. She could not perform this movement with the right hand. At the operation Mocquot freed the triceps tendon and detached it at its insertion into the olecranon. The bones were divided with a chisel, and after resection of the ends he shaped the humerus and radius. Between the articular surfaces a graft of fascia lata was fixed so as to cover all the bony surfaces. Mobilization of the joint was started on the twelfth day, but at the end of five or six weeks there was a period of some difficulty; some reaction was produced and the joint appeared as if about to become re-ankylosed. However, with care and the perseverance of the patient good movement and power in the arm have resulted. Actually flexion of the elbow is almost complete, and the fingers can touch the shoulder, whilst extension is almost full and the joint is quite strong. The functional result is good, especially in an ankylosed joint of inflammatory origin. The radiogram shows, however, that the fascial graft has not completely prevented a certain overgrowth of bone from the bony surfaces.

304. Subungual Yerrucae.

S. AYRES, Junr. (*Arch. Derm. and Syph.*, June, 1922, p. 748) reports two cases in which strikingly satisfactory results followed the use of radium in the treatment of warts growing under the finger-nails. After paring the nail down over the lesion as closely as possible, and protecting the normal tissue with lead foil, 5.5 mg. of radium element were applied, with only paper screening, for twenty minutes in the first case, with two subsequent exposures at fortnightly intervals of forty and thirty-five minutes respectively, making a total of ninety-five minutes' treatment. In the second case only one exposure of seventy-five minutes was given. In neither instance was there any pain, and the greatest amount of reaction consisted of a mild erythema and scaling, and no trace of the lesions could be seen two months afterwards. The advantages of this method over surgical removal, fulguration, or cauterization are seen in the absence of pain, non-interference with function, avoidance of secondary infection, and the complete eradication of the lesion with perfect cosmetic result.

OBSTETRICS AND GYNAECOLOGY.

305. Pelvic Contraction.

ACCORDING to W. ZANGEMEISTER (*Zentralbl. f. Gynäk.*, September 2nd, 1922), the pelvic dimension which is of greatest obstetric significance is the true or obstetric conjugate; this in normal conditions measures, not 11 cm. (this figure being derived from measurements of the bony pelvis), but 10.3 cm., as deduced from measurements made in living subjects. A constant proportion holds good between the true conjugate and the intercrural measurement in all cases of normal or universally contracted pelvis, and the former dimension can be inferred with tolerable certainty if the latter is known. The relations of the two are shown in a straight-line graph, according to which a true conjugate of 10.3 cm. corresponds to an intercrural space of 29 cm., of 9.5 cm. to one of 26 cm., etc. The writer suggests that pelvis (whether flat or generally and equally contracted) with true conjugates greater than 9.5 cm. are not properly to be regarded as instances of pelvic contraction, and suggests classification of contraction in five grades, according as the true conjugate is from 9.5 to 8.6, 8.5 to 7.6, 7.5 to 6.6, 6.5 to 5.6, or less than 5.6 centimetres. At the Marburg clinic 20 per cent. of pelvis are contracted; of these seven-tenths are of Grade 1. According to the author's clinical experience, 9.5 cm. is the lowest limit at which a pelvis may be considered normal; 8.5 cm. the lowest dimension with which spontaneous delivery is, given normal foetal dimensions, to be expected with any degree of probability; 7.5 cm. marks the limit of indication for induction of premature labour; 6.5 cm. is the lowest measurement which, with the help of moulding of the head, can possibly (and exceptionally) permit of living birth of a mature child; and 5.5 cm. the lowest recorded dimension at which a mature foetus after destructive operation has proved susceptible of pelvic delivery. In contrast with the reports usually given, Zangemeister's statistics, based on about 500 cases of birth through contracted pelvis, show that in generally contracted as contrasted with flat pelvis the prospect of spontaneous birth of a living child is better; occipito-posterior and transverse presentations are less common, and premature rupture of the membrane as well as prolapse of the cord or an arm is less frequent. Face presentations, on the contrary, seemed less common in generally contracted than in flat pelvis. The size of the

foetus has a significance with regard to prognosis of labour in contracted pelvis that is frequently underestimated. The foetal mortality in this series was 4 per cent. in children of 4 kg., 30 per cent. in those of 5.5 kg., and 80 per cent. in those of 6.5 kg. With regard to diagnosis of pelvic contraction, Zangemeister remarks that some of the measurements which are advised are both unnecessary and unreliable; careful taking of the true conjugate and intercrural diameters is almost invariably sufficient. The former must be measured directly, not inferred from the diagonal conjugate; there is little difficulty provided the pelvis is contracted and the observer employs a suitable pelvimeter, under anaesthesia if necessary. The true conjugate and intercrural dimensions being known, reference to the graph given by the writer will decide whether the pelvis concerned is generally contracted or flat. Improvement in foetal mortality may be expected from increased use of Caesarean section in selected cases—possibly from development of the technique of operations in which the pelvic girdle is temporarily or permanently widened—but with greatest certainty from judicious induction of early labour, due regard being had not only to the size of the pelvis but also to that of the foetal head. In the first grade of contraction it is not necessary to induce premature birth but to prevent post-mature birth. A true conjugate of 9.5 cm. permits of live birth of a foetus of 3,250 grams; one of 7.6 cm. a foetus of 2,400 grams. With a conjugate of less than 7.6 cm. induction is useless.

306. Syphilis during Pregnancy.

ACCORDING TO W. E. WELZ and A. E. VAN NEST (*Amer. Journ. of Obstet. and Gynecol.*, August, 1922, p. 174), 13.1 per cent. of 1,457 pregnant women attending a prenatal clinic during 1921 were found to be syphilitic, including 19.3 per cent. of the 700 white women. About 90 per cent. of those diagnosed as syphilitic gave a positive Wassermann test, and about 75 per cent. a positive lutein test. Only one chancre was found in the whole series; 20 per cent. of the syphilitics had cutaneous lesions, 29 per cent. markedly impaired reflexes, and 56 per cent. ocular changes. Approximately 85 per cent. of those diagnosed as syphilitic suffered from latent syphilis; none made any complaint of illness, and they visited the clinic only because they were pregnant, the disease being detected during routine examination. Treatment, which was initiated irrespective of the stage of pregnancy, consisted of two injections of mercuric salicylate in oil and one intravenous dose of neo-salvarsan, all given weekly for six weeks and followed, time permitting, after one month's intermission by a second similar course. The 46 patients who received adequate treatment consisting in three or more injections of neo-salvarsan and eight or more of mercuric gave birth to 45 living children and 1 dead child; among the 100 insufficiently treated cases foetal mortality numbered 26. Thirty per cent. only of negative Wassermann reactions were found in the 26 instances in which blood from the umbilical cord was examined in babies whose mothers had had full treatment; the authors do not think it possible, except very early in pregnancy, to prevent by antisiphilitic medication of the mother transmission of the spirochaete to the foetus.

PATHOLOGY.

307. The Haemolytic Functions of Certain Organs.

MAURICE PERRIN and ALFRED HANNS (*Arch. des Mal. du Cœur, des Vaisseaux et du Sang*, August, 1922, p. 552) state that haemolysis has been often studied and its literature is abundant, but the precise determination of the organs which have a haemolytic function is less advanced. They therefore review the knowledge already acquired relating to the organs which appear to possess that function. "The organ which appears to play the greatest part in haemolysis is the spleen." They then review the investigations of the Italian school, and particularly the researches of Banti. These suggest that this function of the spleen is due to the formation of haematin antibodies, or haemolysins. Gilbert, Chabrol, and Bérard have shown that splenic extract is haemolytic; it is not attenuated by heating to 56° C., and is not specific. Other authors deny this and attribute the result to septic infection of the extract. Perrin and Hanns discuss these divergent opinions and suggest that variations may occur as the result of modifications of technique. They state that splenectomized animals show an increased resistance to haemolysing intoxications, and that this serum, added to a haemolytic system, has a greater retarding action than normal serum. The question of a possible haemolytic action of the liver is then discussed. "The liver plays a part in the transformation of the pigment of red corpuscles, but is no proof that it actually destroys the erythro-

cytes; possibly they are broken up elsewhere, notably in the spleen." The authors then discuss the action of bile and of bile salts. Vaquez and Ribierre have shown that in the blood of icteric patients resistance to the haemolytic action of distilled water and of sodium taurocholate is doubled. The part played by cholesterol in haemolysis is then discussed. Cholesterol neutralizes the haemolytic action of the serum of nephritis. The possible haemolytic function of the thyroid and of the suprarenals is then discussed. The authors conclude that it is thus difficult at the present time to come to a final conclusion, and no definite reply to the above question is possible. Some organic extracts have haemolytic properties. Are the substances which confer that property present *in vivo*, and are they specially secreted for a destined end? or rather, is it simply the chemical constitution of the tissue which gives to the extract that haemolytic power? The haemolytic substance in that case may be liberated artificially by the manipulations necessary to the preparation of these extracts.

308. The Leucocytes in Pulmonary Tuberculosis.

O. CALAMITA (*Il Policlinico*, Sez. Prat., July 3rd, 1922, p. 875), as the result of the examination of the blood in 46 cases of pulmonary tuberculosis, came to the following conclusions: The leucocyte count is generally normal in the first and second stages and beginning of the third stage independently of the general condition, the temperature, and extent of the lesions. It is, on the other hand, increased, sometimes to a high degree, in extensive necrotic lesions. It declines again when the cavities are healed or reduced in size. Neutrophilia, as a general rule, goes hand in hand with the leucocytosis. It is therefore associated with the presence of cavities and may be of value in differential diagnosis. Eosinophilia varies with the organic resistance of the patient and is independent of the stage of the lesion. In favourable cases and after recovery the eosinophil quotient is greatly increased, while it diminishes or disappears when the activity of the tuberculous process overcomes the resistance of the organism. No conclusions can be drawn from the behaviour of the mast cells and lymphocytes. The mast-cell quotient does not vary to any extent. The number of the lymphocytes is usually inversely proportional to that of the neutrophils and therefore diminishes considerably in hyperleucocytosis with neutrophilia. The mononuclears follow the behaviour of the eosinophils, being abundant in early or favourable cases and diminishing or disappearing in severe forms of the disease. The displacement of the neutrophil picture, which is only slight at the beginning of the disease, becomes more pronounced with increase in the severity of the case. It is entirely independent of the anatomical nature of the lesion and closely connected with the organic resistance of the patient. Two patients with the same neutrophil picture may not only have different pathological lesions, but may have unequal organic resistance. Every improvement or aggravation of the disease is followed by a shift to the right or left of Arnet's picture. The practical importance of determining the neutrophil picture is therefore very great. It is always a valuable help in the diagnosis of clinical recovery and may prevent a series of disagreeable surprises.

309. Value of the Tuberculin Test.

P. HERTZ (*Ugeskrift for Læger*, July 13th, 1922, p. 837) has investigated the reaction of 88 children to different tuberculin given in different ways. Every child was given, as a rule, seven to eight tests, and 40 of the 88 gave a positive reaction to one or more tests. It was found that the age of the tuberculin used for von Pirquet's test did not affect the reaction, a five-year-old preparation of old tuberculin provoking a lively reaction. The results were also as good with an old tuberculin ointment as with a recent preparation for Moro's innaction test. A comparison of four tuberculin ointments showed that their potency varied greatly; of 38 children giving a positive reaction to Moro's test only 23 gave a more or less strong positive reaction to all four tuberculin ointments. As for the comparative value of von Pirquet's and Moro's tests, it was found that they were at variance in 18 cases; in 11 of these von Pirquet's reaction was positive, whereas one or more of the tuberculin ointments gave a negative reaction. The conclusion to be drawn is that a single tuberculin test, with only one tuberculin preparation, is untrustworthy; and the author calculates that, had he relied on single tests with the least satisfactory tuberculin, 18 of the 40 children giving a positive reaction would have shown a negative reaction. All the children giving a negative reaction to the Moro and von Pirquet tests were given subcutaneous injections of 0.1 mg. of tuberculin, and in all save one the reaction was again negative. This method is therefore the most accurate, but it is not so suitable as the others for tests on a large scale.

LIVERIES AT LOWER PRICES

GAMAGES' LATEST OFFERS!

Among the thousands of Bargains at this Record Sale are these exceptional offers of Liveries. These are standard goods in every way—in material, cut, style and finish. The low price is due solely to our desire to effect a speedy clearance to make room for new stocks. Early ordering is essential to secure

Chauffeurs' LIVERY OVERCOATS

In Dark Navy Blue or Dark Grey, lined warm Tweed, with wind-cuffs in sleeves and cut full length with wide skirt.

SPECIAL PRICE 68/9

In superior quality Melton in Dark Navy Blue, Dark Green and Dark Grey. Best quality warm Tweed lined.

SPECIAL PRICE 85/9

Patterns post free on request. All sizes stocked up to 42-in. chest. When ordering please give size round chest, also height

Chauffeurs' LIVERIES

Consisting of smartly cut Jacket and Breeches in superior quality Melton in Dark Navy Blue, Dark Green and Dark Grey to match our 85/9 Livery Overcoats. Smart and dignified, yet hard wearing, these Liveries are ideal, and for style or value cannot be equalled. We are offering these during the Sale only at an extremely low price, but the cut and finish are in the best Gamage style. Jacket and Breeches.

SPECIAL PRICE 85/9

Patterns post free on request. Please give chest measurement, height, and inside leg when ordering.

20,000 PAIRS MOTOR GAUNTLETS

Final Offer of Huge Government Surplus Purchase

Made from soft Hushido dressed leathers Drab shades. Lined various coloured wool fleece. Large 5-in. gusseted stiff gauntlet, sewed strongest manner possible. Is of mineral tannage, guaranteed to remain soft and pliable and to stand the test of fire, steam, water and washing. Will give excellent satisfaction in wearing. Usually 21/- per pair.

Offered at, per pair
Postage 7d. **5/11**

In ordering state size of gloves worn.

GAMAGES, HOLBORN, LONDON, E.C. 1.

FORETHOUGHT JUSTIFIED!

READ THE FOLLOWING LETTER.

By kind permission of the *British Medical Journal* we reprint the letter below, sent by one of our members and published in the *Journal* of December 10, 1921:—

M.B.Camb., M.R.C.S., writes: "In case any of your readers may be unaware of the existence of the Medical Sickness, Annuity and Life Assurance Society, and the benefits which may be derived from it, I should like to make known to them the following facts: I joined the Society in 1894. In 1900 my health broke down completely, and I could no longer continue to practise. The beneficiary payments of the Society began at once, and have now ceased because I have reached the age limit of 65; but between 1900 and the present time I have drawn 1,096 weeks' sickness benefit for the sum of £2,361, and have paid in premiums £227. My own experience may perhaps induce other members of the profession who are not already insured to consider whether it would not be worth while to follow my example."

Comment is unnecessary, but we would take this opportunity of reminding readers that the Society is available to *all* Medical and Dental practitioners, and the Secretary will be pleased to supply full particulars of permanent Sickness or Accident Assurance.

MEDICAL SICKNESS, ANNUITY & LIFE ASSURANCE SOCIETY

LIMITED.

300, HIGH HOLBORN, LONDON, W.C.1.

The "BARTON" SPHYGMOMANOMETER

possesses the great advantage of being a very active and reliable instrument, extremely light and portable, and always ready for use, those absolute essentials for the apparatus of a busy Medical Practitioner.

Reduced Price ... £3-3-0.

The Surgical Manufacturing Co., Ltd.,

SURGICAL INSTRUMENT MAKERS to the WAR OFFICE, &c.

An Address ON CERTAIN DEVELOPMENTS IN MEDICINE.

DELIVERED AT THE OPENING SESSION OF THE MEDICAL SOCIETY
OF LONDON ON OCTOBER 16TH,

BY
LORD DAWSON OF PENN, G.C.V.O., C.B., M.D.,
PRESIDENT.

PHYSICIAN TO THE LONDON HOSPITAL; PHYSICIAN IN ORDINARY TO
H.M. THE KING; SENATOR OF THE UNIVERSITY OF LONDON.

WE are opening to-night a session of no ordinary importance, in that during its course this society will celebrate its 150th anniversary. And may I here interpolate a personal paragraph and say how honoured I feel to be your President during this year, how deeply I value the confidence which your selection of me donates, and how it will be a "labour of love" to try and serve you well? I shall be encouraged by the example of my distinguished predecessor in the chair—a surgeon in whom the thinker is not lost in the excellence of the technician, and whose wide culture and sympathetic personality give him a large circle of friends.

This society was born at a time of change; an old order in civilization was passing, the forces were gathering which were soon to culminate in the War of Independence—that mighty instrument of liberty which not only brought about the birth of a nation but gave to Britain by its influence a peaceable progression towards the freedom which was to mature in the ensuing century.

The life of this society has corresponded with a period of almost unexampled expansion. Thus in 1782 London had a population of 650,845 and contained 774 doctors, and the College of Physicians consisted of 43 Fellows and 74 Licentiates.* There were no medical schools then, and beyond the training of apprentices facilities for medical instruction consisted of detached efforts by enthusiastic teachers, and such lectures were as often given in private houses as in hospitals. The doctors' residences were extending beyond the City to the then West End, and were exemplified by such addresses as Essex Street, Strand (it was there Dr. Fordyce of St. Thomas's Hospital lectured), Craven Street, Leicester Street, Haymarket. There was no concentration of doctors as in the Harley Street area, and in that respect perhaps our forefathers were wiser than we are.

But this society, being full of youthful vigour, finds more interest in prospect than retrospect, and I have ventured to think that certain tendencies or developments in the art of medicine to-day might be worthy of your consideration; and if I restrict myself to a few of these I hope you will put it down to regard for the exigencies of time and your patience rather than to narrowness of the speaker's outlook.

Developments in the art of medicine are due to—

1. The extension of clinical knowledge.
2. The increasing number and range of the sciences on which the art of medicine is based. To mention these sciences here would be needless—their name will soon be legion. As examples I may refer on the physical side to biochemistry, and on the mental side to psychology. Both of these are making strong claims on our attention—the former in quietude and the latter amidst the noise of the marketplace. In passing I may say that this extending range of medicine makes so big a claim on its devotees as to tend to draw them from contact with the humanities and produce the danger of exclusiveness.

3. Changes in the environment and life of the people. New knowledge brings benefits, but at the same time difficulties of its own. Through modern agencies like the newspapers, and the cinema, and now broadcasting, man's mind is being supplied with a restless stream of impressions which must work into and alter the texture of his mind, especially in youth. We cannot add to the speed and stress of life, as this age is increasingly "doing," without modifying man's behaviour in health and illness. People are kept at high tension, and sometimes as much by their pleasures as by their work, and relaxation becomes a stranger to them, and with the oncoming of wireless telephony and aviation our last hope of peace is going. You are on your way to a consultation, say at Northwood or Walton Heath, having left snitable

messages at home, and behold, you are rung up in your ear on your wireless telephone to say that a patient is arriving from Aberdeen by aeroplane and has to be back at business by the following morning! No escape. These developments disturb life. It is a curious omission that no operation has yet taken place in an aeroplane! The career of the appendix would be incomplete without it, and a cinema operator would have by chance to be one of the passengers.

It results that mind plays a larger part in the causation of disease than in the past; that not only are neuroses more common, but in bodily illness mental symptoms are more often blended with the physical in the clinical picture. What I may style clinical values have changed. Even in organic disease there is commonly a superstructure of neurosis, which is apt to obscure the view. There are, in short, the symptoms more directly produced by the morbid process and the symptoms produced by the patient, and the latter may at times be the more prominent.

As a matter of experience, physicians would, I think, agree that clinical pictures have become more complex, their features more difficult to distinguish and estimate than formerly. And doctors often tell me that in their practices textbook pictures of disease are less and less common. Take that interesting condition, high blood pressure. In its early stage—the crural one—it is often a mental, not a bodily defect. Note the sensitiveness, anxiousness, conscientiousness—all defects of qualities, leading to tenseness of expression and then prematurely to set lines of feature; note also the increased tonic of the muscles with a growing inability to relax them—an inability which will later extend to the hours of sleep.

In our rapid, complex social life exhaustion is not only the direct cause of much disability but its effects colour and complicate the clinical pictures of many diseases. In its manifestations, derangements of body and mind are found in close apposition and interaction. For instance, a tired professional man complains of pains in the heart or dyspepsia. Like many tired people he is hypersensitive and therefore has become over-responsive to the workings of his own vital processes as well as to the jars of the world outside. He then becomes introspective, then possessed of anxiety, and interprets his symptoms in terms of his fears; then follow preoccupation, failure of attention, ineffectiveness in work, loss of confidence, depression, self-depreciation—and so step by step into the zone of danger.

This blending of the physical and mental is illustrated again by certain gastro-intestinal troubles. The patient is usually a spare subject, with keenness and sensibility but without proportionate strength; goes through life "all out," has a shallow frame, a low blood pressure, easily chilled extremities, and an over-responsive abdomen, which reacts to every blast of vain doctrine. What are you to call a complex like this? You must label it by one of its features. Thank heaven for "colitis," but pity the poor statistician. The suprarenal may here be the link, perhaps the "trans former," between mental and physical. The grades and variants are manifold. Such features and factors enter more and more into the causes and manifestations of the illnesses of a modern community.

It follows, therefore (and this is my first plea), that they should not be pushed aside under the general label of "neurotic," nor should they be the exclusive concern of specialists. Rather should they be studied and taught upon in our hospital clinics, and, as they exist, symptoms of mind side by side with symptoms of body.

These problems, which the practitioner has to tackle demand in a special degree the insight and discrimination which come from a bedside training and sympathetic contact with the sick, for the latter have sometimes difficulty in defining their symptoms and have to be understood rather than unduly questioned. Or again, symptoms which may be irrelevant to the immediate physical diagnosis (shall I say the affixing of the label?) may yet be of great moment in that they loom large in the mind of the patient; perhaps have roots in doubts and fears running far back into the patient's life, and need to be perceived, understood, and explained, and thereby dispersed, so that the patient's mind can be given content and confidence, and so reinforce the vital powers which bring about healing. It is this which Goodhart—always perceptive and illuminating—had in mind when speaking of the "Common Neuroses," he said: "There are many conditions in which the cure must come mainly from within, our function in chief being to call out this dormant power."

* *Medicine in England during the Reign of George III.*, by Arnold Chaplin.

The power to penetrate the patient's mind, to help that mind to unfold and to perceive where the burden presses most heavily—all that is part of diagnosis. The resulting confidence and inspiration in the patient's mind is part of treatment.

It is interesting to reflect, how in this as in other respects the arts of Medicine and Education are approximating. The personality of the school child is perceived and understood, and thus encouraged to unfold, and it is led to discipline itself rather than have discipline thrust upon it. In its wider conception treatment is educational, and in the formation of health the territories of Medicine and Education overlap.

Mind training more and more needs to be a prominent aim of both Medicine and Education in order that people may be equipped to deal with the feverishness of their environment. We now have physical culture and training established as a valuable asset of curative and preventive medicine. We now need to give a corresponding place to psychical training. There are in existence the beginnings of such treatment; they are detached efforts, such as relaxation exercises and other measures dependent on the application of rhythm, training in mental detachment, etc. But they need developing and methodizing, and I suggest it is the profession which should do this—not irresponsible though worthy people outside.

These purposes of medical treatment are not new—they have always belonged to the English school of thought; they have been rather eclipsed these later days by progress in the objective methods afforded by radiography, chemistry, surgery, etc. It is curious they should recede into the background at the very time when the conditions of life make their need the greater, and my plea is that Medicine, if it is to fulfil its work, must take mind phenomena more closely into its study and keeping. At the present time they are occupying the public mind too much and the professional mind too little.

PSYCHO-ANALYSIS.

The newer psychology is accepted with seriousness and almost fervour by widening circles of the laity and a group of medical specialists, but at present is regarded with doubt, if not with aversion, by the bulk of the medical profession. At the discussion on psychotherapy at the joint Section of Neurology and Psychological Medicine at the recent meeting of the British Medical Association at Glasgow, physicians attached to hospitals took no part. And is this attitude of mind to be wondered at? What has happened in the past? What is happening now? No sooner does a truth crystallize from honest thinking than it is obscured by encrustations of credulity, assertion, mysticism, and even fraud. Honest exponents drift with fatal facility into exaggerated claims and pretensions, and a superstructure of falsity soon overshadows the foundations of truth, and prejudice rather than conviction is the result.

The way in which all sorts and conditions of people without scientific training or medical knowledge not only discuss but seek to apply analytical psychology would be ludicrous if not so dangerous. And yet psycho-pathology is a serious science with a real and useful application to medicine, and is giving order and direction to methods which were empirical and haphazard. If given a wider recognition and consideration within the fold of medicine, where it would be subjected to restraints and controls, it would "speak forth the words of truth and soberness" and enrich the theory and practice of medicine.

Over psycho-analysis there is much misapprehension. The term comprises (1) the theory of the working of the unconscious mind; (2) the practice whereby the unconscious mind can be explored. Strictly the term should be limited to the particular theory and practice set forth by Freud and his immediate disciples. Many exponents, though accepting the basis of Freud's teaching, have departed from some of his tenets and methods and they seek to distinguish their work by the term "Analytical Psychology." They none the less are saddled by their critics with full responsibility for Freud's teaching, including his view that morbid and repressed complexes are associated with primitive sex impulses.

Though discussion of psycho-analysis is obviously beyond our purpose to-night it is worth briefly considering the ways and means of its presentation and handling, for I venture to think that therein is to be found the explanation of the heavy weather it is encountering.

And here a sharp distinction must be made between its theory and its practice. A theory or hypothesis put forward by a brilliant thinker and supported by a wealth of investigation

cannot fail to enrich knowledge and be for the benefit of mankind, and this irrespective of its truth or falsity, provided it is expounded by those who are fitted to do so—which means, in the case of psycho-analysis, trained workers drawn from the ranks of psychologists, medical men, educationists, and surely it is widely accepted that the theory of the unconscious mind is a great work likely to exercise influence both on medicine and education. But if—as has happened here—all sorts and conditions of people delve into the subject confusion of thought and disturbance of mind must result.

But when it comes to the practice of psycho-analysis a much more serious position arises. Here we are dealing with a highly specialized method of diagnosis and treatment, which cannot be said to be without effect, either for good or evil or both, on the patient. It must often be an exploratory operation on the mind, and if you do not accomplish good you are not sure the result is negative. You cannot feel the same assurance as you do, in the case of an exploratory operation on the body, that at least no damage is done. The mind does not always heal by first intention. May not baneful influences thereby gain entry? Admitting that psycho-analytic treatment has its sphere of usefulness, under conditions of such complexity it is the habit in our profession for the treatment to be undertaken only by workers with specialized training, which ensures skill, restraint, and good judgement (this has been emphasized in a recent paper by Dr. Crichton Miller). Can it be said that these conditions are fulfilled in the practice of psycho-analysis? I fear not, and therein lies legitimate cause for criticism and alarm.

Too many of its practitioners are fanatics, who see neither limitations nor disadvantages and have no eyes for anything outside their narrow cult. This is unfair to competent and serious workers, who thereby get misrepresented, as has recently been illustrated by the joint conference of psychologists and educationists at the recent meeting of the British Association at Hull. I will briefly suggest reasons why psycho-analytic treatment calls for special caution. Its duration is both long and uncertain, extending, it may be, into months and even years. This is a great strain on the mind of the patient, who lives with a quickening sense of his own abnormality, and if the treatment does not suit him the danger of doing him damage is intensified. The operator (analyst) cannot control with precision the range of his operation: beyond the happenings he wishes to induce, others may result which are unsought and detrimental. Psycho-analysis induces and aggravates introspection, and is apt to produce morbid ideas. The laying bare of the unconscious mind—both the process and the result—injures some sensitive subjects and does harm by debasing them in their own estimation.

The dominant position asserted for primitive sex impulses in the causation of repressions aggravates the difficulties of psycho-analytic treatment. All medical men know how difficult is the handling of sex neuroses and aberrations, and how quickly by introspection "sex" will monopolize attention, distort judgement, and pervert conduct. The difficulties on the educational side, where youth is concerned, are even greater. The analyst who holds the Freudian view that the primitive trends of the mind are mostly sexual in origin cannot but be influenced by that bias in the treatment of patients, who likewise will feel its reflected influence.

Lastly, there is a factor in psycho-analytic treatment which presents difficulties of its own. I refer to "transference," which means that emotions and fantasies awakened in the patient by the analysis are detached from their original associations and reincarnated in the analyst, who thus becomes a partner in the life of the patient; or, to quote, "earlier experiences are revived, not as past ones, but in the form of a current relation to the person of the physician."

Is not such a relation of physician to patient putting too big a strain on human nature, and might not positions of danger be provoked? It may be that in practice these difficulties are less apparent, but frank discussion is needed if doubt and misgiving are to be allayed.

Once more the conclusion is the recognition by the profession of the increasing importance of the study of mind in health and illness. Within the fold that study will regain the perspective and restraint which in its present position of isolation it has lost.

HOSTELS OF HEALTH.

Another development in medicine is the growing interest in the beginnings of disease. Within the profession this

interest has received inspiration and direction from Sir James Mackenzie. The conception, birth, and vigour of the Instituto for Clinical Research at St. Andrews constitute the climax of one of the remarkable careers in the annals of present-day medicine. This work is beneficent, not only for the direct results it is achieving, but for its influence in bringing back men's minds to the fundamental importance of studying the patient—a study which had become somewhat overshadowed by the advances in laboratory methods.

From another aspect biochemistry will, I venture to think, more and more throw light on the changes premonitory of disease. By the co-ordination of the two methods of inquiry the surest progress will be achieved.

Corresponding to this trend of thought within the profession there is a notable change in the attitude of the public, in whose mind health has become a positive conception, and is no longer regarded as the same thing as freedom from disease. Strength and perfection of frame are coming to be regarded as both a duty and pride of achievement, and people will pay more attention to digression from this high standard. To be too fat or purple and breathless in the prime of life will be the object of censure, just as now it is considered bad form to have a neglected mouth. As a result—if I may indulge in prophecy—methods of treatment will alter. For these early departures from health will not hostels of health replace hospitals to cure disease?

While continuing his employment the man who is lapsing from anatomical or physiological rectitude will reside in a hostel for a brief space, and under a suitable régime of rest, exercise, diet, training, and other treatment will be restored to the joy of fitness. At present this growing sense of the value of health is too exclusively concerned with the physical aspect. The importance of mind health, however, will in time gain recognition unless its significance is obscured by wild advocacy. And that recognition will be followed by a greatly needed change in the opinions and demands concerning popular recreations and amusements.

ORGANIZATION OF MEDICAL INSTITUTIONS.

In conclusion I will consider, briefly, developments which affect our medical organization.

Growth of medical knowledge and the increasing number of sciences associated with it are steadily making diagnosis and treatment rest on collective rather than individual efforts. Collective effort, to be efficient and economical, needs to be aggregated into organizations. It follows that institutions especially equipped as hospitals and clinics, with their laboratories and accessories, will be necessary throughout the country for all classes if the best that medicine can give is to be at the service of the nation.

If we approach the question from an economic point of view the conclusion is the same. Complexity in diagnosis and treatment means increased cost, and as the cost increases the number of people who can defray that cost grows fewer. The result ensues that from this point of view the more medicine improves the less well are people served. The remedy is clearly massed production, which means institutional organization.

The conditions of family and social life point to the same conclusion. At the present time a large and increasing proportion of the population is not getting the best opportunities in illness. Those who frequent existing hospitals are the rich and the poor, but that large mass of people of moderate means (and with existing taxation the word "moderate" carries increasing emphasis) does not.

This is a reproach. It is unfair to the individual and is to the disadvantage of the community. The public very properly looks to us to say what the remedy should be. Its provision requires the co-operation of the public, but it is for us to indicate its nature and guide its application. Hence the importance of agreement amongst ourselves.

Since the growth of such institutions must be gradual it is the more important that the early ones should be on the right lines, so as to set up a good standard for achievement. I will briefly put forward for discussion some of the conditions which in my judgement should be fulfilled.

I. They should be run on economic but not commercial lines. A fixed percentage (say 6 per cent.) should be paid on the capital and the rest of the profit should go to improving the equipment and usefulness of the institution.

II. The laity should co-operate in the administration. The technical direction should be under a committee of medical men. It would be better for the bulk of the capital not to belong to members of the medical profession. There should

be grades of comfort and luxury to suit varying pockets, but, needless to say, only one standard for all essentials, and that the best.

III. There should be provision for a proportion of patients who cannot defray the cost of their treatment. The cost to all others would be at and above a basic economic charge. Professional fees could be included in, or be independent of, the charges for the use of the institution, but broadly the principle that fees are an arrangement to be made between doctor and patient should be maintained.

IV. Patients attending such institutions would retain their own doctors. The idea must never grow up that these institutions are homes for specialists only. There is an advantage in a consultant having an allotment of beds and his own equipment. That gives him his private workshop and yet he rubs shoulders with colleagues. One-man institutions are a mistake from any point of view.

Should such institutions be built as annexes to existing town hospitals? Speaking generally, and in my opinion, emphatically not. Hospitals are situated where the benevolence and conditions of former days put them. No one would put them in their present positions if building them now. An institution such as I have tried to adumbrate should be near enough to the edge of the city to secure adequate space and air.

Such an idea has been realized in part in a few localities—for example, St. Chad's, Birmingham—but not in its entirety.

Institutions on these lines would solve the problem from the point of view of efficient medical treatment, and also for the people better placed from the point of view of cost. But they would not solve it for the people of small means—say those earning £500 to £600 a year. Such as these cannot even under the conditions above described defray the cost of a serious illness out of income or savings. And yet they must be provided for.

The only way I see is through some system of insurance. A State system of insurance for this purpose is neither desirable nor feasible. I should like to see the big insurance companies take the matter up, and cannot but think they would, if assured that the business would meet a public need and receive strong support. I know there are difficulties, such as the question of adequate control without ruinous charges for supervision, but they should not be insurmountable.

I put forward those suggestions for discussion with the strong conviction that it is for the profession to hammer out the best lines of development and give the public responsible advice.

The discussion to-night might perhaps be usefully resumed at a later date.

THE LIGHT SENSE, WITH SPECIAL REFERENCE TO NAVIGATION.

BY

ANDREW FREELAND FERGUS, M.D., LL.D., F.R.S.E.,
CONSULTING SURGEON, GLASGOW EYE INFIRMARY.

The last fifty or sixty years have seen much discussion and not a little controversy in this and other countries as to the condition of the eyesight of those entrusted with navigation. Even as far back as 1882, when I was in the laboratory of Donders at Utrecht, certain aspects of the same subject were being investigated, for the colour sense of the railway servants was being examined under his direction. It is not my intention to review in any detail the history of the movement, but rather to point out our present position.

As a preliminary I would like definitely to enumerate those functions of vision which seem to me to be necessary for navigational purposes. These are at least four: (1) good visual acuteness; (2) sufficient form sense, or, as I prefer to call it, field vision; (3) approximately normal colour perception; (4) good light sense.

I felt inclined when drawing out the rough outline of this communication also to include binocular vision. A navigator is none the worse of having binocular fixation, but it is by no means necessary, for I have frequently known officers and seamen of the mercantile marine who had each only one useful eye.

It may seem strange to those who have not followed the controversy as to colour testing, but yet it is true, that persons with defective colour perception have been known to navigate

for many years without on any occasion mistaking the colour of lights. The vast majority of colour-blind persons, however, are dangerous, and it is so difficult to define the limits of safety that I do not object to all persons who are definitely colour-blind being rejected by the Board of Trade.

In passing it may be said that there are several factors which enable a colour-blind person to distinguish between the mast-head and port and starboard lights. To begin with, they invariably differ from each other in what may be called essential luminosity—in other words, their kinetic values, if I may be allowed the expression, are different. Much also seems to depend on the form of colour-blindness. Twice during the controversy on colour testing I found myself in acute disagreement with Sir William Abney. In his well-known book on colour-blindness he gave, in the form of spectra, what he believed to be the colour sensations of colour-blind persons. I think the same diagrams also appeared in the report issued by the committee appointed by the Royal Society. Now inspection of these diagrams showed that he represented the warm and the cold ends of the spectrum as occurring in the different forms of colour-blindness as all but invariably distinctly differing in tint. Were that true, then there could scarcely have been such a thing as dangerous colour-blindness. Nor could I agree with the distinct preference which he gave to Holmgren's wools as a test when he gave evidence before the departmental committee of the Board of Trade. He objected to a lantern test on the ground that the colours exhibited by the lanterns were not pure colours; it never seemed to occur to him that the colours of the wools were equally mixed colours. At any rate, I have never found on spectroscopic examination any wool to give a pure colour. Although I do not altogether like Dr. Edridge-Green's recently published book, I do like his lantern; it seems to me to be a thoroughly reliable test, and the Board of Trade has been well advised in adopting it. This, however, is an echo of a past controversy, and is only mentioned because it illustrates that a good light sense may play a part, although only a subordinate part, in the recognition of lights at sea.

In the next place, I will once more enunciate the difference which I drew a considerable number of years ago between visual acuteness on the one hand and the form sense—or, as I now call it, field vision—on the other; for, so far as I can see, the form sense, or field vision, very largely depends on the light sense. To my mind visual acuteness, strictly so called, is the power of reading ordinary small type, and is purely a macular function. It is best illustrated in the following manner. If a person looks at any page of printed matter and fixes a word at the centre of the page he or she will find that, so long as the attention is directed to the word specially selected, the other words on the page, with perhaps the exception of one or two in the immediate neighbourhood, are quite indistinct. That part of the field of vision which is specially adapted for macular vision I have elsewhere called the "field of visual acuteness." It subtends an angle of only a few degrees at the first nodal point of the eye; its shape differs slightly in different individuals, but, roughly speaking, it is more or less circular. So far as I am aware, it has never been thoroughly investigated.

I reserve the phrase "field vision" for a different set of visual impressions. If a person looks at a particular word in the manner already suggested, and studies his own sensations while doing so, he will find that he is quite well aware of other objects in his neighbourhood. Thus he may be aware that there are other people in the room, although he will be quite unable to recognize them. He also may be aware that there is a clock on the wall and see its general shape, although he will be unable to read the time unless he turns the field of vision on the object. All that part of the field of vision which lies outside the field of visual acuteness I call the "field of form sense." It certainly subserves, if I may so say, at least the following functions—namely, the recognition of shape, of colour, and of differences of luminous intensity; that is, it has light sense. As I shall indicate presently, it is this last that is of special importance for certain purposes of navigation.

A single instance will show what is meant by its function of shape. When the person looks at the selected word, if there be other people in the room he will at once be able to tell that the heads are more or less round, and will be able to distinguish the shape of the shoulders and other parts of the body. He will also have a fairly good idea of the form of the different articles of furniture in the room. It is unnecessary to say anything about the colour perception

functions of the periphery of the field, for they are well enough known to every ophthalmic student who has worked at colour perimetry.

Before saying anything about the perception of differences of luminosity in the field external to the macular area there is one line of thought that I wish to introduce at this point. It is perhaps best introduced by the general statement that in most forms of manual work, and in most acts of daily life, the workman uses what, for want of a better name, I have called his form sense or field vision, and not his visual acuteness; so also, in walking along a thoroughfare, it is the field vision that enables one to avoid collision with other passers-by; it is only a small minority of them that we see sufficiently distinctly to make recognition possible. Another very striking example will further indicate my meaning. In the process of coal-mining the visual acuteness is scarcely used at all; it is chiefly the light sense, for that is what is required to distinguish genuine coal from what is technically called dirt. No doubt, if the miner be of a scientific turn of mind and wishes to examine the fossils contained in the coal measures, he will require to use his visual acuteness, but otherwise he carries on his operations by the field vision, and particularly by that part of it which is called the light sense. Two colliers whom I examined recently on account of miners' nystagmus were found each to have an enormous amount of myopia—roughly, about 18 or 20 diopters—and yet, till the nystagmus supervened, they experienced no difficulty in their work so far as vision was concerned.

At the Toronto meeting of the British Medical Association (1906) I instanced a case of another collier who had about 12 diopters of myopia, and who never suspected that there was anything wrong till he tried to get into the service of a railway company. Now in the first two cases there was no visual acuteness possible, in the proper and restricted sense of the term, at a greater distance than three or four inches from the eyes, and in the last case the extreme distance of visual acuteness was not at a greater distance than four or five inches from the eyes.

The above statement, speaking in general terms, is quite true, although I am well aware that it would have to undergo slight modifications were we to proceed to the discussion of the mental interpretation of blurred images—a very intricate subject to which I would most respectfully call the attention of the psychologists. Manual work has little to do with visual acuteness, as I have shown elsewhere; it practically depends on the field vision and on the sense of projection. Failure to realize this important fact may even lead to a miscarriage of justice. For example, in one case which I was assessing with the Sheriff, a surgeon who had seen the patient on behalf of his union reported, "Visual acuteness of the eye is 6/9 Snellen," and not long afterwards another surgeon reported, "The vision of the eye is 6/18." The learned Sheriff, who was arbiter in the case, immediately and very naturally came to the conclusion that if the visual acuteness was at one period only one-half of what it had been a few weeks before the patient was in a bad way. It was pointed out that the certificates were wrong in form, and that the medical examiners could not tell what the vision really was, but could only record what the patient had thought fit to admit in their presence. I further managed to get the Sheriff to realize the important fact that for the work in which this man was engaged visual acuteness was scarcely required at all, but only field vision. The examination of the visual acuteness is a matter of practically no importance in such cases.

Perhaps I may here be allowed to state my strong preference for Landolt's broken-ring types to any others. No doubt Snellen was the first to standardize visual acuteness, and at Snellen was the first to standardize visual acuteness, and at present his types are those which are all but universally employed. Thus visual efficiency is expressed in terms of Snellen's types for the navy and army and for the examinations demanded by the Board of Trade. There is, I think, no doubt that Landolt's tests are much more satisfactory than those of Snellen, although Snellen had the great merit of being the first to standardize visual acuteness in terms of the five-minute angle. Landolt's types are equally useful for literates and illiterates. Moreover, I think something is gained by their being circular in form; by their use we can get much greater uniformity than by ordinary letters of the alphabet, which are more or less irregular in shape. Probably the best proof of the defects of test types composed of ordinary letters is the fact that the letters of the same size in a particular line are frequently not all easily read. The only change I would make in Landolt's types is

to have a good number of each of the sizes of the broken circles printed on the card, the break in the successive members of the same line being put at different angles; either that or to make each of the broken circles to rotate so that the angle at which the break occurs may be varied. I beg respectfully to suggest that the Board of Trade be urged to adopt the principle of Landolt's types and to scrap those in ordinary letters because of the irregularity in each line of the latter.

The investigation of the light sense is a matter which I fear is too much neglected. I think its proper examination would often be most helpful to physicians and to neurologists. Probably it is the first function of the optic nerve to become affected in impending diseases of that structure. I am also of opinion that its examination would frequently reveal such diseases as sclerosis and locomotor ataxy in the early stages; but, so far as I am aware at the moment, it is almost entirely neglected in clinical work in medical wards. In a previous part of this communication I have distinguished between what I call macular vision and field vision, and I think it might be of great utility if apparatus were devised to enable the light sense of both macular vision and field-vision to be thoroughly investigated separately. At present there seems to be little hope of any such thing being done in the United Kingdom. I am not aware of there being anywhere a thoroughly equipped laboratory for the ophthalmic investigation of disease.

The examination of the light sense should be considered under two headings: first, the examination of the minimum light sense; secondly, the examination of the light difference sense; for both of these functions are important as regards the eyesight of seamen. Recently, considerable light has been thrown on this subject by Mr. Percival of Newcastle-on-Tyne, and he has invented apparatus which is probably the best for testing these important functions. Many years ago I devoted some attention to the testing of the light sense. For the testing of the minimum light sense I used what was to all intents and purposes a Forster's light sense box, and for testing the light difference sense I used a spot of light seen double through a rhomb of Iceland spar. The double spot was examined by means of a Nicol's prism, which was arranged to rotate about its long axis, the amount of rotation being indicated in ordinary degrees on a scale. The difficulty of course was to determine the zero with such an apparatus—in other words, the place at which both spots appeared equally bright. This was done by adjusting the apparatus so that they seemed to have the same luminosity; the Nicol's prism was then turned in one direction till the spots appeared to differ very slightly in luminosity, and the point at which that occurred was carefully noted on the scale; the prism was then turned in the opposite direction till again a difference was observed, and the spot at which this occurred was also noted; the point on the scale midway between these two positions was taken to be the zero.

I have no hesitation, however, in saying that Mr. Percival's test is a very admirable one. It is much more easily arranged than the somewhat complicated one I have described, and I think ought to be used by the Board of Trade in the testing of seamen's eyesight. The value of such an examination is perhaps best illustrated by the following incident which occurred in my own experience. Once coming in from the Western Ocean, making for the Clyde, several officers of a steamboat were busy trying on a misty day to see one of the islands lying off the west coast of Ireland. Some of them were quite certain that they had seen it, others altogether failed to see it; that I think was probably due to the light difference sense of the officers who failed to see it being defective. On dark nights in narrow waters where the shore lighting is defective the light difference sense is of the first importance. A person with defective light difference sense on such a night is likely to have great difficulty in determining where the water ends and the land begins. So also it is to be observed that such impediments to safe navigation as icebergs and waterlogged derelicts do not carry lights; a man with a defective light sense will not see these dangers as easily as a man with good light sense. I cannot but regard the matter as being one of extreme importance.

Visual acuteness in the strict sense of the term is of importance in navigation. Thus an officer will not be able to read charts or tide tables or the various instruments used in navigation unless he has good macular vision, nor will the ordinary seaman be able to read a compass card unless he also has good macular vision. It is therefore of great

importance in these respects. The picking up of objects at a distance, such as other vessels or buoys or a land fall, is not necessarily a function of macular vision at all, but is chiefly a function of field vision, and very especially of the light difference sense. The images of most objects seen at sea are not, of course, primarily formed on the macula but on some peripheral point of the retina—in other words, the appeal first comes to the field vision and not to the macular. No doubt in a very large proportion of cases, when a new object appears on the horizon line, and by the field vision the officer becomes aware that it is there, he instinctively looks directly at it to see what it is and thus brings the object into the macular field. If, however, the light difference sense be defective there is a very much increased chance that the new object will not be seen at all, and danger may ensue therefrom. Long years ago I advocated strongly that the light sense of all men entrusted with the duties of an officer of the watch should be carefully tested, but up till now, so far as I am aware, no steps have been taken to bring about this desirable change. At that time the apparatus available was not very suitable, but the circles introduced by Mr. Percival seem to me to leave nothing to be desired.

One other question remains to be mentioned, although I am sorry to say that I am not in a position to give any answer—it is as to the effect of errors of refraction on what I now call field vision. I have already pointed out that very high degrees of myopia do not hinder a man from working, and that satisfactorily, at coal-mining. Navigation, except for the reading of charts and other documents and the necessary instruments of navigation, does not involve, or hardly at all, macular vision, but does involve field vision. The question then arises, Can a man with a moderate degree of myopia safely navigate? I am not prepared to give a dogmatic answer to this important question. At the same time if the myopia be high I think it would form an insuperable barrier to his being put in charge of a vessel. Personally I have provided myself with convex glasses of 3 diopters when at sea, and certainly the artificial myopia induced thereby would have rendered me quite incapable of performing navigational duties. Still it must be remembered that that is an artificial myopia, and that I had not been in the habit of subconsciously interpreting blurred images. On the other hand, I have known a master mariner who commanded a ship for some years, and who had a myopia of about 2 diopters in each eye, a condition which presumably had been with him for most of his life. It is just within the range of the possible that a man who has had for most of his life a fair amount of myopia, and who has been interpreting the consequent blurred images, may be quite fit for navigational duties. The work of a man on the look-out is not a function of macular vision, it is a function of field vision, and although I have no data to go upon, except the case of the master mariner just mentioned, I think it is quite possible that even with a fair amount of myopia the field vision is sufficiently good to render a man safe when on the look-out.

The two points which I desire to emphasize in this paper are: first, that for navigation the light sense should be tested as carefully as the colour sense; and secondly, that most manual work does not depend on macular vision at all, but on what I have called field vision, and that therefore it is idle to attempt to evaluate manual efficiency in terms of visual acuteness as above defined.

THE MECHANISM OF HEARING.

BY

SIR W. M. BAYLISS, F.R.S.

ALTHOUGH from time to time objections have been made to the theory put forward by Helmholtz that the basilar membrane of the cochlea acts as a series of resonators and that by its means analysis of compound sounds is performed in the peripheral receptor organ, it has to be admitted that rival theories present at least as many difficulties. Theories in which this membrane acts as a whole, like a telephone diaphragm, or by "pressure patterns," are inconsistent with the differentiation of structure along the membrane and with the newer knowledge of the conducting properties of nerve fibres. For these reasons the views put forward by Rutherford, Waller, Wrightson, and Ewald cannot be accepted.

In a recent paper Mr. George Wilkinson, F.R.C.S., of Sheffield, also points out that those of Meyer and of Ter

Kuile, if applied to a series of impulsès, really amount to sympathetic resonance. In the paper referred to¹ Mr. Wilkinson describes the construction and properties of a model made with careful adherence to the proportions and nature of the cochlear mechanism. It is by far the most important recent contribution to the knowledge of the problem. Very little attention had previously been given to the experimental investigation of the physics of resonant vibrators immersed in liquid. Professor McKendrick had shown that a series of metallic rods immersed in water was capable of sympathetic resonance, but the system was apparently thought too far removed from the actual structure of the basilar membrane to throw very much light on the behaviour of the latter. Mr. Wilkinson's model is a great advance. It was shown to the Physiological Society in December, 1921, and to the British Association in September, 1922. Details of the mode of construction, in which various difficulties were successfully overcome, must be read in the paper. The mechanician of Professor Leathes's laboratory, Mr. C. E. Stewart, is to be congratulated on the result. It consists essentially of a series of strips of very fine phosphor-bronze stretched across a gap in a brass plate and soldered to this at both ends. The gap is wider at one end than at the other, in order to give a graduated series of different lengths. The strips were first soldered at one end, then stretched by a series of weights, and while under tension soldered at the other end. The whole was then coated with gelatin to form a continuous membrane, leaving a gap at one end (the "helicoctrema"). This structure was made to form the division between two closed chambers of water (the "scalae") into which the two "windows," closed with india-rubber, opened. On one of these a little wooden rod ("stapes") was cemented. The top of the upper chamber was formed by a glass plate. Finely powdered blue enamel was distributed over the membrane to indicate the region of vibration when tuning-forks of various period were applied to the "stapes." The lengths and tensions of the strips, as also the dimensions of the chambers, were carefully calculated, but the vibration rates turned out to be higher than those expected. This is, of course, partly due to difficulties in construction and probably also to the omission of some unknown factors which complicate the formula.

It will be remembered that the rate of vibration of a string depends on three factors. It is directly proportional to the square root of the tension, inversely proportional to the length and to the square root of the mass. As regards the first of these factors, it was early recognized that the difference in length between the fibres at the two ends of the basilar membrane was insufficient to account for the range of pitch perceived, but it was sometimes overlooked that, as Dr. A. A. Gray has shown, there is also a difference in tension, such that the shorter fibres in the membrane are more tightly stretched and the range thereby increased. The mass of the vibrating element was mentioned incidentally by Helmholtz in referring to the membrane being weighted by the liquid in which it lies. But the real importance of this factor was first pointed out by Mr. Wilkinson. He shows that each element of the membrane is to be considered as consisting, not only of the fibre itself and the cells covering it, but also of two columns of water reaching from each element to each window, one on each side. This mass of water vibrates with the fibre, greatly increasing its mass and lowering its rate of vibration. Since the shorter columns are nearer the windows and the shorter fibres of the membrane are at this end of the cochlea, the range of response is further increased, and the reason why the basilar membrane is narrower at the base than at the apex of the cochlea is clear. It is further clear why the membrane must be a continuous one, because, if the fibres had gaps between them, no regular loading of the fibres would be possible.

Passing to the behaviour of this model, it was found that when the "stapes" was touched lightly with a vibrating tuning-fork of 32 D.V. the membrane responded only at one extreme end. Sixty-four D.V. gave a fairly local response about one-third of the way along. To 200 D.V. there was a response at about the middle, below the calculated position, with a partial response at the position for 100 D.V. To 400 D.V. the reaction was close to the calculated point, with a well-marked partial vibration at the 200 D.V. position and a less marked one at that for 100 D.V.

The model is probably capable of further improvement, but it appears that many important investigations might be made in its present form. The degree of damping and the extent of spread of resonance may be mentioned. It may be pointed out that some degree of resonance of adjoining elements is not contradictory to the theory of Helmholtz. The amplitude of vibration of these is probably too small to stimulate the nerve endings. Gray has shown that a similar cutting out of the smaller stimuli occurs in the localization of a point of pressure in the skin.

One fact of interest may be referred to in conclusion. The model responds also to a tuning-fork held in contact with the brass case, just as does the cochlea to conduction through the bone. This indicates that the impulses given by the movements of the stapes are of the same nature as those of sound waves directly transmitted to the water, as would be expected from theoretical considerations.

LUMINAL IN MIGRAINE.

BY

WILFRED HARRIS, M.D., F.R.C.P.,

PHYSICIAN FOR NERVOUS DISEASES, ST. MART'S HOSPITAL, AND TO THE HOSPITAL FOR EPILEPSY AND PARALYSIS, MAIDA VALE, LONDON.

PAROXYSMAL recurrent headaches of hemieral type are so common, and hitherto have been so difficult to diminish either in severity or frequency, that the apparent success of a new remedy which I have been using in this distressing complaint for the past year is, I think, sufficient justification for putting my results before the profession in order that others may test its value, I hope with similar good effect.

The close relationship of true migraine to epilepsy, as one of the paroxysmal neuroses, resembling epilepsy in being preceded often by an aura and succeeded by violent headache, suggested originally the treatment of migraine by prolonged administration of bromides in various forms and combinations. In my hands bromide has practically proved a failure in the treatment of migraine, though in a few cases aspirin, and in others cachets of pyramidon (gr. vii) with cannabis tannate (gr. iij), have notably cut short the duration of the headache if taken immediately after the attack is recognized. Migraine subjects almost invariably visit the oculist before the neurologist, and glasses are often ordered, though very rarely is true migraine improved thereby. Dieting of various kinds, reasonable and unreasonable, is also usually tried, the attacks being spoken of as liverishness, dyspepsia, or bilious headaches. A diet of milk and nuts alone has occasionally been said to cure a tendency to frequently recurring headaches.

Some headaches, doubtless, are of intestinal toxic origin, such as a chronic appendicitis; others, as we know, may be due to errors of refraction, nasal obstruction, pyorrhoea, etc., and may yield to the appropriate treatment. Such headaches must, however, be differentiated from migraine, which in its more characteristic type is notably hereditary, frequently unilateral (hemieral), and often preceded for twenty to thirty minutes by a visual aura known as a scintillating scotoma, with temporary marked diminution of visual acuity. Nausea and vomiting usually follow the headache, sometimes occurring early, often delayed for hours, when the vomiting appears to relieve the headache.

Migraine may alternate with epilepsy in the same patient or in different members of a family, and I have known the same visual aura of scintillating scotoma herald both the epileptic and migraine attacks to which a boy of 13 was subject, whose mother was also a sufferer from migraine. The striking success of luminal in a considerable number of epileptics, who might justly be labelled "bromide failures," is now beginning to be common knowledge, through the writings of Golla and others, though at the same time a few cases, especially in children or young adults, seem to do definitely worse on luminal than on bromide, having more frequent attacks and greater mental torpor. In my experience I have found that it is the epilepsies in children, associated with some organic cerebral lesion, such as an infantile hemiplegia or congenital mental defect, without any family history of epilepsy, that are especially likely not to be benefited by luminal.

In analogy, therefore, with the successful treatment of some of the "bromide failure" epileptics with luminal, it occurred to me to try the effect of this drug in obstinate and frequently recurring migrainous attacks. I may say at

¹ Analysis of Sound by Resonance, *Journ. of Laryngol. and Otol.*, September, 1922. Also a brief account in *Proc. Physiol. Soc. in Journ. of Physiol.*, vol. lvi, p. ii (February, 1922).

once that so far—and I have been using it thus for about a year—I may call its success most gratifying, both the frequency and the severity of the attacks being enormously reduced.

The action of luminal is sedative and hypnotic, and it is chemically a derivative of veronal or of its sodium salt medinal, which is much more soluble. Luminal differs structurally from veronal in that an ethyl group C_2H_5 is replaced by a phenyl group C_6H_5 . Its action is much stronger than that of veronal or medinal, $1\frac{1}{2}$ grains of luminal being perhaps equivalent to $7\frac{1}{2}$ grains of medinal in hypnotic effect.

Luminal is put up in $1\frac{1}{2}$ -grain tablets, or it may be used as a powder in cachet or given in solution. Two examples of its use in migraine may be given as illustrating its effects, though they could be multiplied.

CASE I.

Mrs. X., aged 56, since girlhood always subject to headaches, especially severe at the menstrual periods. Never neurasthenic, but rather phobic. Headaches very severe during last twelve years, and especially frequent during the last three years, latterly every ten or fourteen days. The attacks are preceded by an aura of visual defect, and followed by nausea and vomiting and complete prostration. Each attack lasts two or three days. Any excitement, fatigue, journey, or theatre or other entertainment is apt to bring on an attack. The attacks on the right side are always more severe than those on the left. The menopause became completed about eighteen months ago, but this made no difference to the frequency or severity of the attacks. Intense mental anxiety in December, 1914, appeared to aggravate the headaches and produced sleeplessness, which persisted. All forms of medicinal treatment, massage, and electricity are said to have been tried, without much avail, massage to the back of the neck alone giving some temporary measure of relief. Luminal in $1\frac{1}{2}$ -grain doses, three times a day, was then started, but after a few days the dose was diminished to $\frac{3}{4}$ grain three times a day on account of extreme drowsiness and inco-ordination of movement. The half-dose suited well; she slept very well, and when she reported seven weeks later there had been no attack at all for the past five weeks, and she felt altogether greatly improved and able to take interest in affairs as she had not been able to do for years.

CASE II.

R. P., a man aged 30, has suffered from migraine for the past three years, gradually increasing in frequency, lately every week or ten days, while recently he had four attacks in three days. The attacks are preceded by partial blindness lasting about an hour, which is followed by violent headache for two or three hours. On May 23rd last I gave him 1 grain of luminal, with a little bromide, belladonna, and arsenic three times daily, and up to the present date of writing (August 15th) he has had only one attack, on June 17th, while away on holiday and while he had been without his medicine for ten days. This morning he writes that he has just had an attack of partial blindness, with a feeling of dazed "far-awayness," lasting for thirty-five minutes, but with no headache following, and he is exceedingly grateful for the improvement in his condition.

The dose of luminal should as a rule be not more than $\frac{3}{4}$ grain three times daily at first, and if the result is good the dose need not be increased, but after a fortnight may be reduced to twice daily, and later to once daily, at bedtime. Occasionally larger doses, as $1\frac{1}{2}$ grains three times a day, may be required to produce a good effect, but if this dose is made a routine at the commencement of treatment toxic symptoms will often be met with, such as excessive drowsiness, inco-ordination of the limbs, and a sensation of unreality in relation to surroundings.

After continual administration of the drug for a week or more, various cutaneous rashes may be seen, such as erythema, urticaria, and a macular pink blotchy eruption, perhaps followed by dry branny desquamation. These rashes are unlikely to occur if an initial dose of $\frac{1}{2}$ or $\frac{3}{4}$ grain three times a day is not exceeded.

If migraine or other headaches are associated with sleeplessness, luminal is especially indicated, and $\frac{3}{4}$ grain three times a day will usually give refreshing sleep every night, such as the patients have not known perhaps for many months. This coincident relief of the insomnia and of the distressing headaches is a most striking evidence of the value of this treatment. How long to continue it must be settled by further experience.

At present, after two weeks' administration of $\frac{3}{4}$ grain of luminal three times a day I reduce the dose to twice daily (morning and evening) for another fortnight, and then to a nightly or even occasional dose of $\frac{1}{2}$ or $\frac{3}{4}$ grain for three months or even more. Many sufferers from migraine will, I expect, require to take it occasionally, once or twice a week, indefinitely.

NINETIETH ANNUAL MEETING

OF THE

British Medical Association.

Held at Glasgow, July, 1922.

PROCEEDINGS OF SECTIONS.

SECTION OF ANATOMY.

Professor ALEXANDER MACPHER, M.B., C.M., F.R.F.P.S.,
President.

PRESIDENT'S INTRODUCTORY REMARKS.

THE PRESIDENT, in his opening address, extended a hearty welcome in the name of Professor Bryce and the Officers of the Section to the members assembled from all parts of the country. He congratulated the Council of the Association on having included an Anatomy Section at this meeting: it was good for the scientific side of the work of the Association and it was good for the science of Anatomy. Anatomy must ever remain the very corner stone of medical education and research; yet in these days of a crowded curriculum and growing specialism in science there was danger of the clinician and the anatomist losing touch with one another. He had seen it stated that in our day any attempt at research in human anatomy was comparable to the process of "flogging a dead horse." This might be refuted in many ways, but by none more appropriately on this occasion than by reference to the remarkable presidential address delivered the other evening by Sir William MacEwen; in each advance in the treatment of disease recorded in that address nothing was more striking than the extent to which exact and elaborate anatomical research—on the growth of bone, on the potentialities of the pleural cavity, on the intricacies of the membranes and circulation of the brain—gave the keynote of success to the brilliant series of remedial operations devised by their distinguished President.

He wished, before proceeding to the main subject of his address, to express grateful memories of his teachers of bygone days in the anatomy department of the university where now they met. His revered professor—and "Chief" for several years—John Cleland, was a giant in intellect as in stature; his lectures, though often far above the heads of all but his most brilliant students, were never "dry"; through all there gleamed golden veins of philosophy and poetry and high ideals of work and service; even the most junior student felt from the first that in his classes he had come under the influence of a great and a good man; his creed of industry and discipline was so exacting that incurring his correction was like breasting a mountain burn in flood; but his anger was quickly subsided, and the exceeding kindness which followed more than compensated for the spate of terror. The wonderful record of his research and exposition—accomplished at a period when mechanical aids were few and imperfect compared with modern resources—cannot be adequately dealt with here: but a saying of the late Professor D. J. Cunningham might be recalled, with which he ended a review of Cleland's Textbook, that the high quality and the great diversity of Cleland's work might well elicit, in the breast of any anatomist, feelings both of admiration and of despair.

He wished to congratulate Professor Bryce very heartily on the happy thought which led him to group together in his museum the anatomical preparations of William Hunter, Allen Thomson, and John Cleland. No Anatomy School in the world could claim a richer heritage. He suggested that it would be a graceful act to direct the Secretaries of the Section to send a cordial greeting of its esteem, with the affectionate remembrance of those members who had been his students, to Emeritus Professor Cleland, who had adorned for so many years the Chair of Anatomy in the University whose hospitality they were now enjoying.

He desired also to voice the gratitude and affection with which all their old students in this University regarded Yule Mackay and Bruce Young, the most distinguished among Cleland's assistants, and in conjunction with whom he issued the notable volume of *Memoirs and Memoranda in Anatomy*. The hope that a second volume would appear—rich in the same high level of observation and research—was, unfortunately, never fulfilled; the recognition of his great administrative ability by colleagues in University College,

Dundee, and of his practical grasp of educational ideals and problems by the General Medical Council, had robbed science of the continuance of the valuable researches achieved by Principal Mackay, particularly in the development of the arterial system; and Bruce Young, whose early work on the anatomy of joints shook the science of Arthrology to its foundations, was all too soon diverted by ill health from a career full of brilliant promise for the progress of the Science of Anatomy.

DISCUSSION ON THE ADMINISTRATION OF THE ANATOMY ACT.

OPENING PAPER

BY

PROFESSOR ALEXANDER MACPHERSON, M.B., C.M.,
F.R.F.P.S.

IN introducing a discussion on this subject, so vital to medical education, the President described how the first steps towards new legislation were taken at a joint meeting of the Anatomical Society with the Anatomy Section of the Association at the Annual Meeting in London in 1910, when the late Professor A. M. Paterson was President and he himself was Secretary. As the result of a discussion on the vexed question of the difficulty of securing an adequate supply of anatomical material in all parts of the country, a special meeting, to which all licensed teachers were summoned, was held in the Royal College of Surgeons, London, in the following December; an "Anatomical Supply Committee" was appointed, to gather full information about the problem, and to recommend, if possible, some efficient remedy.

The Anatomical Supply Committee.

The late Professor Alexander Macalister was elected chairman of this committee, which was representative of teachers of anatomy and operative surgery in all parts of the (then) United Kingdom and in His Majesty's Services; it included Professors Arthur Thomsen (Oxford), R. W. Reid (Aberdeen), Arthur Robinson (Edinburgh), the late A. M. Paterson (Liverpool), Johnstone Symington (Belfast), A. F. Dixon (Dublin), F. G. Parsons (London), Mr. W. McAdam Eccles (London), Colonel E. M. Pileher (R.A.M.C.), and himself as honorary secretary. The committee held many meetings, and conducted widespread investigations into the conditions of anatomical supply both in this and in other countries, and early in 1912 issued a report summarizing these, and recommending that His Majesty's Government be approached by a deputation to explain the difficulties commonly experienced in the working of the Anatomy Acts of 1832 and 1871 and to suggest suitable amendments or the introduction of a new Act. A second meeting of licensed teachers, to which this report was submitted, empowered the committee to organize as influential a deputation as possible, on the lines suggested.

1912. Deputation at the House of Commons.

In December, 1912, the Right Hon. Reginald McKenna, M.P., Home Secretary, received at the House of Commons this deputation, which he described as "literally and truly unparalleled and unprecedented." It included representatives from every university and medical licensing corporation in the United Kingdom; in most cases their Vice-Chancellors attended to represent the former, and their Presidents the latter; it was introduced by the Right Hon. Dr. Christopher Addison, then recently elected a Member of Parliament. The pressing needs of the anatomy schools, and the disastrous effects that would befall medical education and practice unless efficient teaching in anatomy were maintained, were explained in speeches by the late Principal Sir William Turner, the late Professor Alexander Macalister, Sir Rickman Godlee, the late Sir Alfred Pearce Gould, Sir Thomas Barlow, Colonel Skinner, Principal Sir Donald Macalister, and Principal Sir George Adam Smith. In reply, the Home Secretary declared himself deeply impressed by these speeches, and he carefully discussed the points raised; he avowed a further attempt to improve the administration of the existing Act rather than run the risks of introducing a new one, but he undertook to face the latter course if nothing resulted from the efforts that would be made to improve the conditions.

1913. Conference at the Home Office.

At Mr. McKenna's request a subcommittee of the licensed teachers not representatives of several Government departments in conference at the Home Office early in 1913. While the Scottish Office and the Scottish teachers were represented at this conference the Irish Office, then, expressing the desire to be informed of its views, did not send a representative. At this conference several suggestions for improving supply were discussed; there was general agreement that the institution of a "notification fee" was desirable, to be paid to the executive officers who were responsible for the careful and exhaustive inquiries which led to the certainty of an unclaimed body being available, but any practical outcome was delayed owing to the principal official concerned being engrossed by new legislation in another sphere, and no improvement had taken place when the following year witnessed the outbreak of war.

Though sadly disappointed by this delay, the committee could not then press this matter on a Government suddenly burdened by such tremendous problems and responsibilities. Moreover, the mobilization or voluntary enlistment of many students in the early days of the war and, later, the practical conscription, under the Derby scheme, of all medical students who were fit for military service, lessened the difficulties of the schools. It became necessary, indeed, to close some of the sources of supply and also, owing to the surplus which had accumulated, to introduce an Order extending by twelve months the period during which a subject might be retained before burial.

1918. The Post-war Crisis.

The end of the war, however, led to a crisis in the difficulty of supply. The return of large numbers of students who had happily been spared to resume their studies, and, concurrently, a large increase in the number of new students, led to the crowding of dissecting rooms by men and women for many of whom no subjects could be provided for practical instruction in anatomy, while the teaching of operative surgery on the cadaver had to be entirely suspended. Late in the year 1918, thus faced with difficulties even greater than when they commenced their labours, the committee again approached the Home Office and were referred from there to Sir George Newman, one of the medical representatives of the Government at the Conference in 1913, who favoured steps being taken to transfer the administration of the Act to the Board of Education on the ground that this Ministry had become closely concerned in the problems of medical teaching through the allocation of grants, which would largely fail of their purpose if an adequate supply of material for anatomical teaching and research were not maintained in the universities and medical schools.

Meantime, while steps in this direction were in progress, suggestions had reached the committee from various quarters that as this problem closely affected, through the provision of properly trained medical men and women, the health and well-being of the country, it should be undertaken by the new Ministry of Health then in process of establishment, and early in 1919 the committee decided to recommend that course. A memorandum was prepared by the committee, embodying all their previous efforts to find a remedy for the deficiency in anatomical supplies, and this was forwarded to the Prime Minister and other members of the Government with the twofold recommendation that the administration of the Anatomy Act should be among the powers and duties to be transferred to the Ministry of Health and to the Scottish Board of Health, and that the Act should be amended in such a way that it would adequately effect the purpose for which it was originally framed. In the first of these recommendations the committee was assured of the cordial support of Dr. Addison, the first Minister of Health, who was personally acquainted with the difficulties of the situation through his former experience as a professor of anatomy.

1919. Transference of the Administration of the Anatomy Act from the Home Office.

In September, 1919, an Order in Council was prepared, advising the transference recommended by the committee. Owing to the somewhat cumbersome procedure required by both Houses of Parliament the Order did not take effect until May 17th, 1920, on which date it received the approval of the King in Council, but the subcommittee of licensed teachers, who had lately lamented the loss of their chairman, Professor Alexander Macalister, and had appointed Professor Arthur

Thomson in his stead, had meanwhile been invited to meet the Minister of Health in conference, in November, 1919, to discuss immediate steps that might be taken to remove the difficulties of the medical schools of England and Wales. The problem as it affected the medical schools of Scotland was the subject of discussion, about the same time, between the Scottish Office and the Scottish Board of Health, when it was decided, he understood, that in Scotland the administration of the Act should remain, as heretofore, in the hands of the Scottish Office.

Administration of the Act by the Ministry of Health.

The Minister of Health explained to this conference that the transference of the administration of the Act by Order in Council gave the Minister of Health no powers to alter in any way the regulations of its various clauses, and he proposed, in the first instance, to inaugurate a systematic approach to the legal custodians of unclaimed bodies; for he was assured, by inquiries he had made, that if all such as were available were placed at the service of medical education the requirements of the schools could be adequately met.

It was therefore decided to make an effort to realize the purpose of the existing Act by inviting himself (the President) to accept office as a medical officer of the Ministry, in the hope that his close acquaintance with all the preceding negotiations would enable him effectively to explain to the authorities concerned the difficulties of the administration of the Act, and, by his long experience in the practice of anatomy, to impress on them their opportunity of advancing the cause of medical education. That office the President accepted in July, 1920, as soon as he could be released from his duties at St. Bartholomew's Hospital Medical School; and after consultation with Dr. Addison and his chief medical officer, S.r George Nowman, he proceeded at once to organize a new campaign on lines approved by them.

Thus, for the first time in the history of the administration of the Anatomy Act in England and Wales, a Government department undertook the responsibility not merely of supervising the anatomy schools, but also of helping them to secure an adequate supply of the material which they require.

The gravity of the situation at that time might be judged by the following figures: the University of Cambridge had 3 adult subjects available for the tuition of a class of 280 students; Liverpool had 2 for 253; Cardiff 2 for 220; Bristol 2 for 118; Manchester 6 for 250. While the London medical schools suffered from an equally marked deficiency, the other provincial universities were more adequately supplied; the new campaign was therefore directed in the first instance to improving the conditions in London and the foregoing provincial areas—conditions which had led inevitably to a return to primitive methods of instruction; oral demonstrations had to be substituted for dissections, which had to be eked out sometimes by using the bodies of stillborn children, or even of monkeys as in the days of Galen. In this course of action much help was derived from the previous labours of the London Anatomical Committee (chairman, Sir Arthur Keith; secretary, Professor F. G. Parsons), of the Provincial Committee (chairman, Professor Arthur Thomson, Oxford; secretary, Professor J. S. B. Stopford, Manchester), and of Mr. W. O'Sullivan, who, on the staff of the Home Office, had for many years carried on the work of the Anatomy Office prior to its transference, with that Office, to the Ministry of Health.

The policy adopted by the Ministry closely followed that pursued by the licensed teachers over the long period since the introduction of the Anatomy Act, by appealing to the legal custodians of unclaimed bodies for the use of these for anatomical examination.

This policy was based on careful consideration of the view that the systematic use of such bodies for medical education was the method least likely to give offence to the sentiments of living persons.

[The President then explained in full detail the methods adopted in the administration of the Act.]

1920-1922. The Effect.

The results recorded amply justified the policy of the Ministry, and the conviction of the first Minister of Health that all the requirements of the medical schools could be met, for the present, without recourse to new legislation. The number of institutions, asylums, etc., which had thus been added to the former sources of supply amounted to a total of 127, and from these many subjects had been distributed to

the schools. Translating the records into terms of the usual allocation of "parts," in the classes of anatomy and operative surgery it might be said that more than 12,000 students had thus enjoyed for one term at least the opportunity they would otherwise have lost of thorough tuition and experience in the fundamental science of their profession. In terms of the benefit to be derived in the long run by the people of this country, the improvement was incalculable.

The Future.

With regard to the future, it was well to realize that there were difficulties ahead. That anatomical subjects would be required by the medical schools as long as disease prevailed was as fundamental a fact as that knowledge of the alphabet was the first step in any scheme of education, elementary or advanced. There could be no doubt, however, that all the beneficent measures now directed towards improving the conditions of life were resulting in a gradual diminution in the number of unclaimed dead. This question brought him to a very important aspect of the administration of the Act.

Clause VII of the Anatomy Act expressly provides for the carrying out of the wishes of persons who "direct" that their bodies shall be used for anatomical examination after death. In past years many such, rich and poor alike, had advanced the cause of medical education by so doing. He had commonly heard the statement, even from those most bitterly opposed to the idea of permitting the dissection of other persons, that they felt no objection whatever to their own bodies being used in that way. In this sentiment lay the crux of the whole question of the voluntary bequest of bodies for the benefit of medical science, and due regard was paid to it in the safeguards qualifying Clause VII, which gave any surviving relative the right to annul the bequest by requiring the body to be interred without such examination. Anomalous as this might appear at first, when contrasted with the binding nature of any bequest of personal property, it was surely realized, on second thoughts, as a right and proper protection of such sentiments of living people, regarding the disposal of the dead, as might be a much deeper matter to them than interest in merely material affairs. The suggestion had frequently been made that an adequate supply of subjects would be assured were such bequests made legally binding on executors through an amendment of the Act. Not long since Lord Rowallan, in a letter to the *Times*, expressed his surprise on learning that he could not legally bequeath his body for the relief of human suffering by the advancement of medical knowledge, and his opinion "that no obstacle should be put in the way of those who feel that being serviceable is every where honourable to a man while he lives and to his body when he has left it."

No suggestion yet made, however, could overcome the present state of public sentiment and the difficulty that while a deceased person had passed beyond any concern in the matter, there might be living persons whose feelings it was not right to disregard by insisting on the manner of the disposal of his or her remains. At the root of these feelings might lie, no doubt, the aftermath of the sinister days when the horrors of "body-snatching" and the exaggerated horrors of the dissecting room which gathered round them were a present fear to every household in the land. There still persisted, too, that view of the sanctity of the corpse which made the idea of its dissection appear irreverent; the life of the great Vesalius, the father of human anatomy, was sacrificed to that feeling close on four hundred years ago, and it had not entirely disappeared even in our own day.

While it was probably true that any member of our own profession—though most familiar of all, therefore, with the meaning and purpose of anatomy—could think with equanimity of his own body being dissected, should it be required for the advancement of medical science, it was probably equally true that in the present stage of our outlook on these matters he could not think exactly in the same way with regard to the bodies of his nearest relatives. How much more likely must we expect this to be true in the case of laymen in general, until such time as the sting of death and the victory of the grave should have lost their potent influence on the human mind.

But smoky signs were not wanting of a steady advance towards a day when the material aspect of death would be seen in proper focus, and in these there appeared to him to lie the assurance that the teaching of anatomy, if its requirements were adequately presented, would never lack the public support it needed. The ever-increasing number of persons directing that their bodies should be cremated surely denoted

the gradual progress of enlightened views as to the facts of death; and it should not be difficult to persuade such persons, and their relatives, of the advantages to medical science and their fellow men which would result from a prior anatomical examination. The grim horrors of war, too, had done much in our time to hasten the "dying of death"; it mattered little, surely, compared with the revered memories of the fallen, whether his flesh were torn by wounds or dissipated by a shell, whether his mortal remains lay in the Abbey or in a distant field in Flanders. Might not those signs of an altering outlook on the fact of death be interpreted as the gradual growth of a common-sense view which would gradually remove the mass of distressful mystery which has for so long surrounded it? And might not one result be that, when the need arose, all the bodies required for medical study would be freely supplied by voluntary dedication? He felt convinced that in the vanguard of such dedication would be found the men and women of the medical profession.

DISCUSSION.

Professor T. H. BRYCE (Glasgow) said he had been most interested to hear the account of what Professor Macphail had accomplished for the medical schools south of the Tweed. It was comforting to learn of the success that had attended his work for the Ministry of Health. In Glasgow there was an ideal arrangement, established since a long time, by which the matter was supervised, under the Inspector of Anatomy, by a committee consisting of the senior magistrates with representatives of the Poor Law authorities and of the Public Health Department in consultation with the teachers. In spite of this, and of a special clause in the Public Health Act, serious shortage of subjects was experienced notwithstanding the goodwill of the authorities. Many causes probably combined to this effect. The amelioration of the social conditions of the people tended to reduce the supply; and the only thing to do was to add to the number of the sources. This was being actively carried out by the Inspector of Anatomy, with improving results. The propoundance in hospitals and asylums of *post-mortem* examinations on unclaimed bodies—except in exceptional circumstances—should be forbidden. In times of serious shortage when it was impossible to provide adequately both for anatomical and for operative surgery classes he thought it would be universally agreed that the students of anatomy should have the first claim, as nothing could make up for the loss of the experience gained in the practical anatomy class. This was not so much because the mere facts could not be acquired otherwise, but because in no other way than by personal dissection could the student acquire a permanent and working knowledge of the structure of the body.

Professor J. T. WILSON (Cambridge) said that, speaking as a teacher of anatomy in England, he desired to express his grateful appreciation of the efforts made by the President of the Section in his capacity as a Medical Officer of the Ministry of Health. As a result of his work the provision of subjects for the teaching of anatomy in the Cambridge school had been placed on a satisfactory basis. He was grateful to the Ministry for placing an expert in control of these matters. He strongly supported the President's view of the undesirability of claiming for anatomical purposes the bodies of the inmates of Poor Law institutions on the ground of pauperism. It was, he held, of the utmost importance for the future of the practice of anatomy to remove from it any stigma of pauperism. In older days the stigma of criminality was attached to the practice of dissection, when practically the only subjects available were the bodies of executed criminals. This has long ceased to be the case, but the stigma of pauperism still remained to a great extent, inasmuch as it was, and must always be, the case that the majority of unclaimed bodies were those of the impecunious. Yet we must hope that social evolution would progressively diminish the actual amount of pauperism, whilst the requirement of bodies for dissection would always remain a stringent necessity for scientific education. In his view the hope for an adequate provision for the future must lie in the removal of all stigmata and in the growing recognition by an enlightened public opinion of the truth that it was not only possible, but a worthy aim, to be of service to the community after death by authorizing during life the disposal of one's body in furtherance of the interests of medical science.

Professor J. C. BRASH (Birmingham) desired to add his testimony to the remarks of the Senior Vice-President as

to the valuable work which had been accomplished by the President of the Section. In Birmingham the supply of subjects had been slowly but steadily going down until Professor Macphail had visited that area, and now it is steadily increasing, owing, of course, to his having made available a supply of unclaimed bodies which would otherwise have been lost. He felt very grateful for the President's careful exposition of the difficult question of compulsory as compared with voluntary action in this matter.

On the invitation of the President, Professor THOMAS WALMSLEY (Belfast), who had visited the Section to listen to the discussion, spoke of the conditions of anatomical supply in the north of Ireland, where a new inspector had been appointed now that they were separated from the south. In the consequent reorganization, while things were still largely in a state of flux, they had proceeded along lines modelled for the most part on those followed by the President in England and Wales.

The PRESIDENT, having replied to questions raised by the other speakers, then closed the discussion, and called upon Professor J. T. Wilson, F.R.S., the Senior Vice-President, to occupy the chair during the hearing of the subsequent papers. He had already expressed to their distinguished Senior Vice-President his own sense of the anomaly of presiding over any gathering of which he (Professor Wilson) was a member, and he knew that the Section would welcome to the chair a man of his wide experience and scientific attainments.

THE RELATION OF THE URETERS TO THE VAGINA*:

WITH A NOTE ON THE ASYMMETRICAL POSITION OF THE UTERUS.

By JAMES C. BRASH, M.C., M.A., B.Sc., M.B., Ch.B.,
Professor of Anatomy, University of Birmingham.

The relation of the ureters to the vagina is recognized to be one of the most important points in the topographical anatomy of the female pelvis. The accounts of this relation in most textbooks, however, are found to be in very general terms. Most agree in stating that, after passing obliquely downwards, forwards, and inwards, usually in close relation to the lateral fornx, a portion of the ureter lies in front of the vagina. Variations in the length of this pre vaginal portion of the ureter are recorded, and there seems to be some opinion that the relation of the ureter to the vagina is more intimate on the left side. But a clear statement of the distinction between its two parts, between the vagina and the bladder and in the wall of the bladder itself, is lacking, and it does not appear that the very frequent distinct asymmetry of the relation on the two sides has been specifically noticed.

The general assumption appears to be that, as the cervix and the trigone of the bladder are relatively fixed, there is no asymmetry in this region, and that the only factor to be considered with reference to this relation is the state of the bladder. Distension of the bladder undoubtedly produces slight differences in the position of the two ureters relatively to each other, and, as they separate, the amount of each in relation to the anterior wall of the vagina necessarily diminishes. But we can leave this factor practically out of account; the amount of spreading of the trigone is very little compared with the rest of the wall of the bladder. Given a bladder and vagina symmetrically related to each other, no amount of distension of the bladder will carry the ureters beyond the anterior wall of the vagina. One of the ureters, however, is frequently found not to reach the side of the vagina, and the cause of this is a permanent displacement of the uterus and upper part of the vagina relative to the middle line of the trigone. It is generally conceded that the uterus lies asymmetrically in the pelvis, in the majority of cases with the fundus inclined to the right, the cervix correspondingly to the left, and the body rotated so that the right Fallopian tube is nearer the anterior abdominal wall than the left.

* This paper was originally directed to this question in 1914 by a Leeds University, to make some note on "Fistulae in the female pelvis."

the surgical importance of the point demonstrated. I am indebted to Professor Heller for permission to include the former findings.

FIG. 1.—Multipara, aged 59. Half natural size. $a-b = 19$ mm.; $a-c = 14$ mm.; $b-c = 13$ mm.; $a-a' = 12$ mm.; $b-b' = 8$ mm.

FIG. 2.—Para, aged 39. Half natural size. $a-b = 27$ mm.; $a-c = 18$ mm.; $b-c = 21$ mm.; $a-a' = 12$ mm.; $b-b' = 10$ mm.

FIG. 3.—Multipara, aged 37. Half natural size. $a-b = 20.5$ mm.; $a-c = 23.5$ mm.; $b-c = 16.5$ mm.; $a-a' = 15$ mm.; $b-b' = 14$ mm.

FIG. 4.—Para, aged 57. Half natural size. $a-b = 31$ mm.; $a-c = 35$ mm.; $b-c = 33$ mm.; $a-a' = 14$ mm.; $b-b' = 23$ mm.

FIG. 5.—Para, aged 43. Half natural size. $a-b = 21$ mm.; $a-c = 20$ mm.; $b-c = 20$ mm.; $a-a' = 12$ mm.; $b-b' = 1$ mm.

FIG. 6.—Para, aged 52. Half natural size. $a-b = 19$ mm.; $a-c = 24$ mm.; $b-c = 22$ mm.; $a-a' = 8$ mm.; $b-b' = 7$ mm.

FIG. 7.—Aged 14. Half natural size. $a-b = 15$ mm.; $a-c = 30$ mm.; $b-c = 30$ mm.; $a-a' = 9$ mm.; $b-b' = 10$ mm.

FIG. 8.—Aged 11. Half natural size. $a-b = 17$ mm.; $a-c = 20$ mm.; $b-c = 13.5$ mm.; $a-a' = 7$ mm.; $b-b' = 10$ mm.

FIG. 9.—Fetus, full-term. The arrows show the direction of pressure as described in the text. Half natural size. $a-b = 5$ mm.; $a-c = 10$ mm.; $b-c = 15$ mm.; $a-a' = 15$ mm.; $b-b' = 15$ mm.

FIG. 10.—Fetus, seven months. Half natural size. $a-b = 5$ mm.; $a-c = 10$ mm.; $b-c = 10.5$ mm.

No elaborate description is required. A study of the accompanying illustrations will demonstrate the point it is desired to establish. The method of investigation has been to remove the pelvic contents entire, fix in formalin, and open the vagina from behind and the bladder from the front. The position of the trigone in relation to the vagina was then marked by passing pins from the bladder to the vagina at the three points—one through the floor of the bladder immediately above the internal urethral orifice, and one through the middle of each of the oblique ureteral openings. The position of the trigone is thus mapped out and the lengths of the portions of the ureters in relation to the vagina seen at a glance. A dissection of the ureters to the points where they entered the bladder wall completed the preparations. The series of outlines given are taken from these preparations, and represent the vagina opened from behind; with

the position of the trigone marked in relation to its anterior wall. In each case a is the left ureteral opening, b is the right ureteral opening, c is the urethral orifice, and a' b' the points at which the ureters enter the bladder wall. The drawings are to scale, and the measurements in each specimen are given with the figure.

When there is an approximately symmetrical arrangement (Figs. 1 and 2) there are, as a rule, on both sides two distinct parts of the prevaginal portion of the ureter, a part lying in the connective tissue between the vagina and the bladder and a part in the wall of the bladder. Testut states that these parts vary from 15 to 18 mm. and from 10 to 15 mm. respectively. So far as the present dissections go, the actual length of the part of the ureter in the bladder wall varies from 7 to 23 mm., and of this the whole or none may be in front of the vagina. The part in the connective

issue between the bladder and the vagina varied from 1 to 36 mm.

Figs. 3 to 6 show increasing amounts of relative displacement of the trigone to the right, which is the condition usually found. In Fig. 6 the intimate relation of the left ureter to the lateral fornix and the long prevaginal portion on that side are in striking contrast to the condition on the right, where the ureter is not in close relation to the vagina at all.

It should be noted that the differences in shape and position, which are such a marked feature of the age changes in the bladder as a whole, are accompanied by corresponding differences in the shape of the trigone and its position relative to the uterus and vagina. Figs. 7 to 10 illustrate these points, and it will be noticed that the trigone not only changes from an isosceles shape characteristic of the foetus to the approximately equilateral shape which is characteristic of the adult, but that its position as a whole moves down from the region of the cervix to the upper part of the vagina. This relative descent precedes to a variable extent, as may be seen from the figures, and as may be indicated by the statement that the vertical distance from the os uteri externum to the interureteral line varies in the adult specimens examined from 6 to 23 mm., with an average of 12 mm.

There is no doubt that the asymmetry is established in the later months of foetal life while the bladder and uterus are still abdominal organs, and that it is due to pressure from the colon as it becomes distended by meconium from the seventh to the ninth month. I am inclined to think, judging from the relation of these parts in a number of foetuses of different ages, that it is a question of balance between pressure on the fundus of the uterus and on the bladder by the loop of colon (which becomes the iliac colon) situated in the left iliac fossa and the loop (which becomes the pelvic colon) situated in the right iliac fossa. The latter is well known to vary in length, and in the foetus, moreover, it passes into the true pelvis to become continuous with the rectum from the right side. By exerting pressure on the cervix from the right it thus accentuates the asymmetry of the uterus. The specimen from which Fig. 9 was taken furnishes an excellent illustration of these factors. There are three well-marked pressure facets on the uterus, a large left and small right on the fundus, and a large right on the cervix, corresponding to the parts of the colon mentioned. There is marked asymmetry of the uterus, the cervix being pushed to the left and the fundus to the right, and the bladder is also displaced to the right.

The subsequent greater relative descent of the bladder into the true pelvis will naturally accentuate that asymmetrical relation of the trigone to the uterus and vagina which is already present, and when the bladder reassumes a median position as it expands into the anterior hollow of the true pelvis it is easy to see that it will tend to rotate the uterus on its long axis. The same process therefore accounts not only for the "normally" asymmetrical position of the trigone of the bladder and of the ends of the ureters in relation to the anterior vaginal wall, but also explains the "normal" position of the uterus with reference to the middle line of the body.

Lastly, it may be noted that variations in the lie of the lower part of the colon, distended with meconium, in the foetus will account for the observed variations in the final position of the uterus and of the trigone of the bladder and the ureters in relation to the vagina.

Symmary.

1. The relation of the last portion of the ureter to the vagina is variable. There is usually a portion of the ureter in front of the vagina, lying for a short distance in the connective tissue between vagina and bladder and then in the wall of the bladder itself.

2. With the vagina and bladder symmetrically related to each other this portion of the ureter is equal on the two sides; but deviation from the symmetrical position is the rule. The result is an increase of this portion of the ureter on one side and a corresponding decrease on the other. There is frequently no ureter in front of the vagina on one side and therefore a much longer portion than usual on the other side.

3. In the majority of specimens examined it is the left ureter that has the greater relation to the vagina, and it is occasionally found crossing the middle line of the vagina.

4. As a rule, therefore, the left ureter is in a position of greater danger than the right, both in operative work and from the point of view of the formation of a uretero-vaginal fistula as a result of pressure. It must not be forgotten, however, that occasionally the position may be reversed.

5. The "normal" asymmetrical position of the uterus in the pelvis is explained by the fact that an asymmetrical position of bladder and uterus is early established while these organs are still in their abdominal situation, by the subsequent greater relative descent of the bladder and its reassumption of a median position in the true pelvis which accentuates the asymmetrical position of the uterus and rotates it around its long axis.

DISCUSSION.

Major S. ENGLISH, speaking from the point of view of the surgeon, said that he wished to congratulate Professor Brash on his paper. Professor Brash had cleared up what had been a matter of considerable difficulty in the performance of operations. The speaker would now be far less afraid of injuring the ureter.

Professor Wilson expressed his appreciation of Professor Brash's investigation. It was important to ascertain the range of variation of various structures in the body and much work remained to be done on these lines. He questioned whether pressure was the cause of the asymmetry of the trigone as well as of the downward movement of the trigone. Asymmetry of the trigone was present very early. The genital ducts were also uncertain in position. The change in form and proportion of the trigone might be due to interstitial growth.

Professor BRASH, in reply, said that there were two lines of variation—lateral and vertical. Both the bladder and uterus descended into the pelvis, but the bladder might descend relatively lower. Lateral pressure caused the uterus, cervix, and vagina to assume an asymmetrical position. Then when the bladder descended the asymmetry was accentuated. The change in form in the trigone was due to interstitial growth. He was glad to know that his work had a practical application to surgery.

THE ANATOMY OF THE BONE MARROW:

WITH SPECIAL REFERENCE TO THE DISTRIBUTION OF THE RED MARROW.

BY

A. PINEX, M.R.C.P. LOND., M.R.C.S. ENG.,

Lecturer in Pathological Histology, University of Birmingham.

THE subject of this communication is not original in conception, but is designed to supplement and, in some cases, modify the accounts previously published. The standard textbooks of anatomy make only indefinite statements on the subject of the anatomy of the marrow; this is probably due to the lack of opportunity in the dissecting room for the observation of the changes associated with advancing age. The textbooks of haematology, in which one might well expect to find the required information, are filled with cytological details and theoretical considerations as to the genealogy of the blood cells, but the essential facts of the ordinary macroscopic anatomy of the bone marrow are not described; brief statements of more than doubtful accuracy are found which appear to have been copied from book to book. The absence of information on the normal anatomy of the bone marrow is the justification for the present paper.

The red bone marrow is the principal haematopoietic tissue in the adult and is not only a simple material serving to render the bones solid without unduly increasing their weight. It is the factory in which all the formed elements of the blood are produced with, perhaps, the exception of the lymphocytes. Disorders of the red bone marrow are associated with irregularities in the production of anti-substances, and it would appear that the red marrow is the principal arsenal of the defensive forces of the body.

Since the demonstration of the haematopoietic function of the adult bone marrow by Bizzozero¹ and Neumann² there have been a number of descriptions of the changes in the distribution of the red marrow throughout life. The first paper of value dealing with this subject was that of Neumann, in which he pointed out that the older idea that the epiphyses contained red marrow while the diaphyses contained fatty tissue was incorrect. He found that the small bones of the hands and feet contained fatty marrow in the adult, as did also the tibia, fibula, radius, and ulna, whereas the humerus and femur contained a small area of red marrow at the upper epiphysis. His material was insufficient to enable him to describe the distribution in childhood. His conclusion was

that the fatty metamorphosis commenced in the most distal parts of the limb bones and spread towards the trunk; this appeared to him to be in agreement with the observation of Raviar that the caudal vertebrae of tailed animals contained fat.

Hedinger⁵ published results similar to these based on examination of over five hundred cases, but, like Neumann, he only considered the distribution in the adult, and his description dealt only with the marrow of the femur.

It would appear as if this older work had been forgotten or ignored, as many quite recent authors make very different statements without giving any reasons for their deviation from these classical accounts. W. K. Hunter⁶ stated that in the adult the red marrow was limited to the ends of the long bones, the ribs, and the skull, thus leaving the reader to infer that both ends of each long bone contained red marrow. Gruner⁷ made a similar statement regarding the long bones.

The haematopoietic function of the red marrow is, apparently, not yet realized by all authors. Ord⁸ asked, "Why should marrow be only for the nourishment of a bone?" He would thus appear to believe that the modern conception of the functions of the marrow has not advanced in any particular since the time of Galen, who regarded the marrow as the nutritive tissue of the bones. Ord, however, made other statements of more importance to the present subject; thus in the same letter from which the above question is quoted he states that "most of the marrow in the human body is in the femur, and next to the femur the humerus, and following them the long bones in this order: tibia, fibula, radius, ulna. One femur contains probably a sixth of the marrow in the whole body." He does not state at what age the femur contains this amount of marrow, nor does he state how the relative amounts are estimated. It will be obvious from these few references to the literature that the red bone marrow is the only organ in the human body of which the normal size at different ages is still unknown. In this paper I will try to present the facts as determined by ordinary observation in the post-mortem room, but I can make no contribution to our knowledge of its weight, either relative or absolute.

The present investigation deals with material from 91 subjects between the ages of 3 days and 83 years.

Technique.

The selection of material for the study of the normal distribution of the red bone marrow requires great care; only material from cases of sudden death in previously healthy persons can be employed. When one recalls the haematopoietic function of this tissue, it is obvious that any condition requiring an increased number of cells, either red or white, in the circulation will lead to changes in the red marrow which may be sufficiently intense to be obvious on macroscopic examination.

The best method of examining the long bones is by making a longitudinal cut with a narrow-bladed hack saw, which obviates the blurring of the appearances which is inevitable if an ordinary flat saw is used. The corresponding bone of the opposite side should be examined by a series of transverse sections at various levels. The examination by transverse section, is necessary to demonstrate the fact that the red marrow is more extensive at the periphery of the medullary cavity than in the axis.

It is well to realize that red tissue in the medullary cavity is not necessarily true cellular red marrow. Microscopic examination is essential for the determination of the limits of the true cellular marrow congestion of the blood vessels in an area of fat closely simulates the appearance of true marrow. Microscopic examination also enables an estimate of the relative cellularity of the tissue to be made, as minute amounts of fat are not macroscopically appreciable.

The arrangement of the bony trabeculae can be investigated in specimens which have been washed under the tap until the marrow tissue is completely removed. This process takes two or three days. The ribs can be examined by longitudinal section, and some additional information can be obtained by expressing the marrow with strong forceps. The vertebrae can be inspected by removing the anterior part of their bodies.

The technique as described above is applicable to examinations in the post-mortem room, but obviously a much more extensive investigation is possible in the dissecting room where aesthetic considerations need play no part in the selection of a method.

The Long Bones.

It is impossible to describe each case in this series in detail, and only a summary of the findings will be given. If the material is selected with the precautions suggested above it will be found that the amount of individual variation is very slight.

At birth and during the first three or four years of life the cut section of the marrow is pink in colour, but the expressed tissue is a rich red colour. The pinkness of the section is due to the presence of closely set bony trabeculae which divide up the tissue into small masses. As the age of 7 is approached the marrow is a less bright pink and the cut surface is more greasy. The expressed tissue is now also a less definite red, and glistening droplets of fat are distinctly visible. The bony trabeculae in the shaft are less well developed and are farther apart.

The changes in the diaphyses and in the epiphyses are best considered separately from this age onwards.

Diaphyses.

Up to the age of 7 there is increasing greyiness of the marrow although it is still pink in colour, but no macroscopic areas of fat are present. Between the ages of 12 and 14 a patch of fat becomes visible about the middle of the shaft, and within the next twelvemonth there are a number of smaller patches in the part of the shaft below this first patch. The changes in the tibia and fibula are similar in character to those in the femur but occur more rapidly; similarly the changes in the radius and ulna advance more rapidly than those in the humerus.

The patch of fat in the middle of the shaft grows both distally and proximally in each bone, but the growth in the former direction is more rapid in all the bones. By the time that the fatty metamorphosis has reached both ends of the tibia and fibula it has also reached the lower end of the femur, but not its upper end; there is a similar distribution in the upper extremity. Thus at this stage the distal bones contain only fatty tissue in their diaphyses, while the proximal bones have still a patch of red marrow at the upper end of the shaft. This is the adult condition of the shafts of the long bones.

Throughout these changes there is progressive diminution in the number of bony trabeculae and also decrease in their rigidity. Incomplete bony trabeculae are always present in the fatty tissue, but are almost completely absent from the patch of red marrow at the upper ends. This absence of trabeculae appears to be associated with the functional activity of the marrow at these places.

The importance of examination of transverse sections of the shaft consists in the fact that the red marrow extends farther down at the periphery of the medullary cavity than it does in the axis. If a transverse section of the fatty patch which appears at puberty, be examined in this way it will be seen that the periphery is red.

Epiphyses.

The changes in the epiphyses are of a similar nature to those in the diaphyses, but occur as a separate process of fatty metamorphosis, and are not associated with absorption of the bony trabeculae. At the age of 7 the lower epiphyses of the distal bones show macroscopically detectable fat, and by the time of puberty there is much fat in both epiphyses of the distal bones of both upper and lower extremities and an appreciable amount in the lower epiphyses of the proximal bones and a little in their upper epiphyses. The fatty change in the epiphyses is complete by the age of 19 or 20 in all the bones, although a few small patches of red marrow may be visible throughout life.

In extremely advanced age no red marrow may be detectable in the epiphyses, and even the diaphyseal patch may be almost completely metamorphosed. It is rare to find any difference between the limb bones of the two sides, but it would appear that the humerus of the adult contains a large quantity of cellular marrow than does the femur.

It must be understood that the transition from red to fatty marrow is diffuse in all the bones and is not sharply demarcated. The apparently complete fatty change in all the bones is shown, by microscopic examination, to be less extensive than would appear macroscopically, as there are always islets of blood-forming cells left.

Tarsus and Carpus.

The number of these bones which have been examined is too small to justify a definite account of the changes, but the

no observation which may be recorded is that the fatty metamorphosis is complete before the whole of the marrow of the diaphyses of the tibia, fibula, radius, and ulna is fatty.

The Ribs.

The ribs are the great storehouses of cellular marrow in the adult, but changes are detectable with advancing age; the marrow adjacent to the cartilages usually becomes fatty about the age of 25 for a distance of about an inch. The only indication of fat in the remainder of the bone is in the grey colour and in the presence of glistening globules in the expressed tissue. On longitudinal section of the ribs a darker patch is usually visible at the angle. Incidentally it may be mentioned that it would appear that this is the place in which cellular marrow persists longest in conditions of pathological aplasia of the marrow.⁹

Vertebrae.

The marrow of the vertebrae is red throughout life, and is traversed by very firm, close, bony trabeculae. In only one case was fat seen in the vertebrae with the naked eye, and this was in a woman aged 83; in this case no fat was seen above the third lumbar vertebra, and there was distinctly more fat in the uppermost segment of the sacrum and the fifth lumbar vertebra than in the third lumbar; it will be recalled that this would be homologous with the condition observed by Ravvier in tailed animals.

Sternum.

The sternum contains a good deal of red marrow and the trabeculae are well developed. Fat is not usually detectable except as glistening droplets in the expressed tissue.

Os Innominatum.

This bone is very similar to the vertebrae, inasmuch as it has very firm bony trabeculae and fat is very rarely seen, the red marrow persisting throughout life.

Ectopic Formation of Marrow.

Bone marrow of typical cellular structure is occasionally noted in other parts of the body than the medullary cavities of the bones; in some cases this occurs in pathological conditions such as leukaemia where there is demand for undue numbers of blood cells, but it has been seen in the normal adult. Bone marrow has been noted in the pelvis of the kidney. This has been seen in a normal adult male, but is more frequent in leukaemia¹⁰ and pseudoleukaemic anaemia.¹¹ The appearance of this tissue is not unlike that of blood clot, and its nature can only be determined with certainty by microscopic examination.

Lymphatics.

The lymphatic supply of the marrow has never been demonstrated, and since the publication of Roger and Josué,¹² who definitely denied its existence, no author has suggested the presence of such channels on experimental grounds, although there have been suggestions of their presence from no clinical side. In the present research the technique was similar to that employed by Dewey and Noyes,¹³ who verified the existence of lymphatics in teeth. The material used for injection was Prussian blue ground up with ether and argentine.

Injection direct into the marrow tissue through the injection cannula described by the above authors resulted in the filling of the blood channels. If the blood channels were first injected with a carmine-gelatin mass, it was not possible to cause the Prussian-blue suspension to pass along the marrow, even when great force was employed.

If the lymphatics of the periosteum are injected the injection material does not pass into the marrow tissue, but is stopped at the endosteum after passing through the compact bone. Even if force is employed it is not possible to send the injection material into the marrow tissue; the only result of the employment of force is to cause extravasation into the endosteum. The writer has pointed out elsewhere¹⁴ that the earliest metastases of carcinoma in the marrow of the long bones are always situated at the upper end of the diaphyses of the proximal bones—that is, in the red marrow. Later metastases in the bones also occur in the red marrow which has spread along the medullary cavity, owing to the irritation of the metastases or the state of cachexia. At one time it was commonly believed that these bone metastases were transferred by retrograde permeation of the lymphatics of the tendons of attachment of the great muscles,

but at present Handley is one of the few authorities who take up this position. Injection experiments performed by the above technique are in absolute opposition to this theory.

Blood Vessels.

Injection of the blood vessels of a freshly killed experimental animal presents no difficulty if the channels are first washed out with saline, and then a warm carmine-gelatin mass is used. Bones obtained from the *post-mortem* room require to be warmed to body temperature before they can be used, and, in addition, it is necessary to wash out the vessels with a fibrin solvent such as sodium sulphate solution.

The injection is best made from the main artery of the limb. The injection mass is found in the nutrient artery which branches frequently in the medullary cavity. It breaks up into a leash of vessels at the lower edge of the red marrow at the upper ends of the diaphyses of the limb bones. This sudden widening of the stream-bed may account for the localization of metastases in this position, as their intravascular situation has been demonstrated by the writer.¹¹ The small vascular channels of the red marrow are doubtless very variable, as their endothelium almost certainly functions as a haematopoietic tissue when necessary, and, when it does so, there must be a change in the distribution of the small channels.

In the infant where the whole marrow is cellular, and also in the rabbit, the tissue is penetrated by similar small vascular channels. The rabbit differs in some particulars of unessential character, such as the possession of a central artery partially surrounded by a venous sinus in the axis of the tissue.

An injection of the blood vessels of the marrow of the normal human adult femur shows well-defined vessels in the fatty tissue, but the cellular tissue is all a definite carmine red; this applies only to the macroscopic appearances. Microscopically the carmine-gelatin mass is seen to be confined to the closely packed blood channels of the red marrow, and is not extravasated into the surrounding tissue. In the fatty tissue the vessels can be dissected out as well-defined red cords.

Application to the Routine Teaching of Anatomy in the Dissecting Room.

These observations are of only limited applicability to the routine teaching of anatomy in the dissecting room because the subjects are almost invariably very old and have died of chronic wasting diseases. The amount of red marrow in the majority of subjects in the dissecting room is very small, but the ordinary methods of preserving bodies are quite satisfactory for its demonstration. The marrow of the ribs and vertebrae is well seen.

The Size of the Marrow at Various Ages.

This subject has been investigated by Wetzel¹⁵ with a complicated technique of uncertain value. His results, which have not as yet been repeated by the writer, are as follows: at birth the marrow is about 11 times as large as the spleen, and by the age of 19 is 12.9 times as large as at birth. The relation of marrow and spleen is said to be unchanged during this time. This last statement is presumably incorrect, as the spleen is not 12.9 times as large at the age of 19 as it is at birth.

Conclusion.

In brief, the picture of the marrow changes throughout life, as observed macroscopically, is as follows: from infancy to advanced age there is progressive diminution in the relative amount of cellular marrow in the limb bones and progressive increase in the amount of fat.

Examination of a series of adult marrows would lead one to imagine that there had been centripetal spread of the fat, thus leading to the filling of the more distal parts of the long bones with fat. This was the conclusion arrived at by Neumann.³ Examination of the limb bones of a subject between the ages of 16 and 18 might lead to the belief that the red marrow was mainly confined to the ends of the long bones. The adult condition of the distribution of the marrow is reached about the 25th year, but some of the bones reach their final distribution at an earlier age.

The arrangement of the blood vessels in the red marrow is the essential factor in haematopoiesis, the two main types of cells—namely, red and white—being produced in relation to different parts of the vascular system of the marrow. The changes in the marrow of other animals are not well known,

but Ackerknecht¹⁰ has shown that the changes in the distribution of the red marrow in the horse are very similar to those described above as being normal in man.

DISCUSSION.

Dr. BATTERSBY (Glasgow) asked Dr. Piney if he could say what determined the progress of the fatty change. Why did it begin at puberty?

Dr. GRAHAM (Glasgow) emphasized the importance of Dr. Piney's work. Medical students had as a rule no clear conception of the anatomy and functions of the bone marrow until they came to study pathology. He now cut up bones as a routine in the dissecting room. Many of these were, however, found to be abnormal, and it was difficult to learn the normal condition from them.

Professor WILSON said that Dr. Piney's extensive series of observations would be appreciated by anatomists. They usually had not the opportunity of examining the stages of development of bone marrow. He would like to know whether Dr. Piney had studied the microscopical changes. Probably the alterations in structure at different periods depended on vascular change. As regarded teaching, the material in the dissecting room was not good as a rule. He suggested that bones of animals should be used.

Dr. PINEY, in reply, could give no reason why the spread of the fat in bone marrow should take place mainly distally, but the same phenomenon was seen in the tails of animals. He did not think gravity had anything to do with it because the change began just below the middle of the bone. It had some relation to the nutrient artery. The changes which took place in the vessels at the same time were very complicated, but their cause was unknown. He had not dealt with the microscopical details owing to lack of time. The first appearance of perivascular fat was associated with thickening of the vessel wall. Probably it occurred as a result of decreased vascular supply.

RADIOLOGY IN THE TEACHING OF ANATOMY.

BY

J. M. WOODBURN MORISON, M.B., C.M.GLAS.,

Honorary Radiologist to Manchester Royal Infirmary; Lecturer in Applied Anatomy, Manchester University.

For many years anatomists have used radiographs in the form of plates, prints, or lantern slides to illustrate their lectures and demonstrations. In Manchester we have gone a step farther, and Professor J. S. B. Stopford has equipped one of the rooms in the anatomy school for x-ray work. He has attached me to his teaching staff as radiologist, and I am proud to hold that post.

I shall now briefly outline what we did last winter, showing you some of the lantern slides and prints used in the demonstrations, and I hope to convince you that the radiologist may be of use in the teaching of anatomy under the firm but kindly guidance of its professors, and thus may repay in some small measure the debt he owes to the anatomist.

I would lay stress first of all on the fact that attendance at the x-ray demonstrations is not compulsory. Nevertheless,

they are well attended by students, who probably regard them as a relaxation from their more strenuous studies. These demonstrations are so arranged that they are related to the general scheme of teaching; therefore the students come with some knowledge of the subject, forming a critical audience.

It may be that I sometimes create doubt in their minds: for instance, when screwing a chest they see in the right anterior oblique position a clear, well-defined space lying between the heart and the vertebral column—the posterior mediastinal space. The difficulty of the student is to reconcile what he has seen on the fluorescent screen with what he sees in the dissecting room, but these little problems are interesting and teach him to think out things for himself and approach the anatomy of the living, which he cannot do from dissections of the cadaver alone.

The first demonstration naturally deals with the discovery of x rays by Röntgen in 1895, the invention of the focus tube by Sir Herbert Jackson of King's College, which made the application of x rays in medicine a practical problem, and a few words are added about the two great pioneers of radiology in England, Sir James Mackenzie Davidson and Mr. Thurstan Holland. In the early days technique had to be acquired by the experience of many failures; nowadays it is taken for granted—apparatus has been so improved and standardized that anyone of average intelligence can learn to take good radiographs in a few weeks' time. It is the interpretation of them which is difficult, and for which a knowledge of anatomy is so essential.

We proceed to show how x rays penetrate objects in direct proportion to their density, passing through air with practically no resistance, but more or less completely stopped by lead according to its thickness. The different densities of human tissues are considered and also the action of x rays on the fluorescent screen and photographic plates. The student is now in a position to understand that he is not studying a photograph in the ordinary sense of the term, but a series of superimposed shadows which require interpretation.

We then go on to the x-ray study of a long bone and explain how the series of superimposed shadows is produced. We note that the periosteum does not give any shadow, but how in periostitis the deposition of calcium salts soon takes place and a shadow is seen. The cortex is seen giving a dense shadow and the cancellous bone a less dense one. The medullary canal morgan at the ends into the cancellous heads is explained and also the cartilage space. The importance of knowing the structure of bones and the blood supply of the bones is illustrated by radiographs showing how osteomyelitis and how a secondary carcinoma affect a bone, and the moral of the tale is plain: you cannot interpret a radiograph correctly without a knowledge of anatomy.

In subsequent demonstrations we discuss the growth of bone and study the normal, but the abnormal is also shown, for it emphasizes the necessity of a knowledge of the normal, and the student at the very beginning of his anatomical studies learns that the knowledge he is laboriously acquiring will be of use to him and is really necessary in his after career.

In the dissecting room last winter a student said to me: "But it is only if you are going to be a surgeon that you require anatomy—apart from examinations, of course!" I think this idea can be dispelled by the teacher of anatomy if he uses illustrations of the abnormal in his teaching. Let me give you an illustration: After studying the normal position and movements of the diaphragm on the fluorescent screen, if you show a student an abnormal diaphragm he becomes interested and finds that there is a delightful anatomical problem to be worked out.

In one of the photographs which we show is seen a necrosis of the parietal bone, and the story of how the whole bone was torn out with the scalp by a revolving belt and later on replaced by the doctor in the hope that it would be all right illustrates strikingly the blood supply of that bone.

After the bones and joints we demonstrate the chest. The students screen each other and learn the normal x-ray appearances of the lungs and heart. The alimentary tract is full of interest. They take bismuth meals and observe the passage of food through the oesophagus, the shape, size, tone, and position of the living stomach, the passage of food through the small intestine, and the appearance of the colon. The urinary tract is also dealt with, and slides of pneumoperitoneum work form interesting research student also finds that radiograph.

in many ways—for example, in investigating the blood supply of different organs.

We have only made a beginning in Manchester. There is still much to do and infinite scope for development—for example, in stereoscopic radiography. In conclusion, I would urge that radiology is of use in the teaching of anatomy, inasmuch as it gives the student some idea of the structure of the living body which he can compare with his work in the dissecting room. He becomes aware that his anatomical knowledge will be of use to him in his everyday work as an intelligent practitioner of medicine. Radiology makes anatomy of the living possible, and its use in the teaching of anatomy brings the anatomist and the radiologist into a communion which is, I think, mutually helpful, and from which, at any rate, I have derived great pleasure and benefit.

[Dr. Woodburn Morison's paper was accompanied by the exhibition of a number of lantern slides and prints, illustrating what was being done in Manchester.]

DISCUSSION.

Professor MACPHAIL congratulated Dr. Morison on his correlation of x-ray work with anatomy. It was a great help to students to show them how structures worked.

Professor WILSON envied a department which had its own x-ray apparatus. He was in the habit of using x-ray plates, and had found stereographic plates particularly useful. It was not likely at the present time that many anatomical departments could have their own x-rays, but they might arrange to share the apparatus of another department.

THE STRUCTURE OF THE VERTEBRATE HEAD.

BY

W. B. PRIMROSE, M.B., Ch.B.,

Extra Dispensary Surgeon, Western Infirmary, Glasgow; lately Senior Demonstrator of Anatomy in the University of Glasgow.

THE problem of the morphological structure of the vertebrate head does not seem to have received scientific attention until Goethe, prompted by the appearances presented by a sagittally divided sheep's skull, suggested the idea of modified vertebral structure for that of the vertebrate head. The cranial axis appeared to him to be composed of several modified vertebrae which all possessed more or less modified arches passing over the brain and under the gut-tube. This suggestion (1790) was never published by Goethe himself, but thirty years later, a contemporary, Oken, published an account of the subject corresponding very closely with that of Goethe.¹

Without going into details of history, it may be stated shortly that the morphology of the vertebrate head has alternated between extreme views of segmentation (Frobie, van Wijhe, F. Bringer, and others) and extreme views of non-segmentation (Hübner² and others). Here it is intended to show that the structure of the vertebrate head is based upon the first metameric segment of the body, with which is combined an unsegmented structure which is called the face.

Owing to the limitation of space, it will not be possible to give more than a brief description of the structure of the vertebrate head. Much of the evidence has to be omitted, but if the morphological principles to be stated immediately are followed their application to the problem will not be unduly difficult.

The principle followed in this discussion is that structures arising in the same morphological position, at the same period of evolution or of development, and in the same manner, are homologous structures, and they form a morphological unit. Structures which differ in respect of their origin may be anatomically and physiologically identical, but they are never homologous. This principle eliminates errors due to anatomical relations and appearances, which are variable, but as the origin of the same kind of structures is always constant, we can infer homologies between the structures which will be constant for all forms in which they occur, irrespective of the anatomical variations which homologous structures may present.

When a structure is formed it acquires relations of two distinct kinds. The first or primary relation is that which a structure bears to the structure which gave rise to it or which was responsible for its formation. This relationship is constant and may be called the morphological relationship. It is obvious that there is only one primary or morphological relationship for any structure—namely, that of offspring to parent. The second kind of relation is that which a structure bears to

any or every other structure. Such relations are secondary (anatomical), and they are variable to an endless degree.

As the result of applying this principle of identity of origin and of relationship to the skeleton of the head, it is found that this skeleton consists of four morphologically distinct skeletons which are not separable anatomically. In other words, there are four skeletons which arise in different morphological situations, at different times, both in evolution and in development, and in different ways. In order of appearance they are:

1. The sclerotome skeleton.
2. The axial skeleton.
3. The splanchnic skeleton.
4. The facial skeleton.

The *sclerotome skeleton** is the first tissue skeleton to appear in evolution, and it is first formed at the time when the somatic or body-wall mesoderm became segmented for the purpose of acting upon the segmented hydrostatic or water skeleton contained in the coelomic sacs in the Annelida. The mesoderm thus segmented is said to be metamERICALLY segmented (Fig. 1). At this stage we might give two definitions concerning segments.

FIG. 1.—Diagram of the hydrostatic skeleton, showing also the segmented condition of the somatic mesoderm and its attachment to the periphery of the coelomic septa which later become the sclerotomes.

A mesodermic segment consists of that portion of mesoderm that is related to one coelomic cavity, and which is repeated in every metameric segment of the body.

A metameric segment consists of all the structures of epiblastic, mesoblastic, and hypoblastic origin related to one coelomic cavity, and its segmented and segmental structures are repeated serially in every unmodified metameric segment of the body. (The term "segmented" is applied to the condition of the paraxial mesoderm or to the hydrostatic skeleton, while the term "segmental" indicates the arrangement of non-segmental structures relative to a mesodermic or a metameric segment.)

When the hydrostatic skeleton disappears from the coelomic cavities during evolution the septa separating the coelomic compartments remain and continue to give attachment to the segmented body-wall muscles. In fishes these septa become the sclerotomes which give attachment to the myotomes, and they also become modified by the deposit in them of rigid

matter forming incomplete arches or arcualia (Gadow). An examination of Fig. 1 will show that each muscle segment is attached before and behind to a fibrous septum. When arcualia appear, they too are twice

FIG. 2.—A, Arrangement of nerves and blood vessels relative to the arcualia in *Petromyzon* in the hinder trunk region. B, Same as A but from the anterior trunk region (Graham Kerr, after Schanz). C, Arrangement of the nerves and blood vessels to the arcualia in the head region of vertebrates generally. a, Anterior, and b, posterior arcualia. d.r. and v.r., Dorsal and ventral nerve roots. b.v., Blood vessel. N, Notochord.

* For a more complete account of this skeleton the reader is referred to the *Journal of Anatomy*, vol. lv, parts 2 and 3, January and April, 1921, pp. 119-137.

as numerous as the muscle segments—Cyclostomata and Dipnoi (Fig. 2, A); but as evolution progresses all the "anterior" arches disappear from behind forward (Fig. 3, B), leaving the posterior arches, which become the neural and costal or visceral arches of vertebrates generally. This skeleton is the only one that is primarily segmented in accordance with the metameric segmentation of the mesoderm.

The sclerotome skeleton is best recognized in most vertebrates by the cartilaginous or osseous arches it develops. There are two sets of these arches: those passing dorsally over the neural tube are neural arches from their anatomical relations to that structure, and those passing ventrally in the body wall are the costal or visceral arches from their anatomical relations. The morphological relations of these arches are to myotomes only.

The head segment, being the first segment in the body, is very primitive and presents the anterior and posterior sclerotome arches

FIG. 3.—This shows the changes from the condition of double arches and vertebrae to that of single arches and intervertebral discs. C, The corresponding changes in vertebral axis of the head.

neural and visceral arches are being formed, and the manner of their origin is from before backwards, so that the trabeculae and Meckel's cartilages appear first, the occipital and hyoid arches next, then the remaining arches in the same order. This does not apply so definitely to osseous origin, especially of ribs, as their extreme specialization confers upon them priority of appearance which upsets the primitive sequence.

It will be seen, then, that these arches form the anterior and posterior supports for a single myotome (Fig. 2, C), but as development proceeds in the osseous vertebrates the anterior arches—the trabeculae and Meckel's cartilages—disappear (Fig. 3, C), their place being taken by another skeleton. The sclerotome skeleton of the head segment is now like that of all other segments, having a single neural arch (occipital) and a single visceral arch (hyoid).

The axial skeleton is the next skeleton to appear in evolution and in development, and it first appears as the notochord, which is an unsegmented rod of cells of hypoblastic origin. It extends throughout the length of the segmented portion of the animal's body, giving support to the many segments. The notochord presents certain characters which render it unfit to act as an axial skeleton in its unmodified condition, and to overcome these drawbacks the perinotochordal mesodermic sheath forms rings of rigid matter which, by encroaching upon the notochordal tissue, convert the notochord into a segmented axial skeleton.

This segmentation has at first no relation to the metameric segmentation of the sclerotome skeleton, there being as many as four rings per segment as in the Holocephali. It is only later that the perinotochordal segmentation comes to correspond with that of the sclerotome skeleton, resulting in the formation of ring-like vertebral centra with which the sclerotome arches

combine. Referring again to the primitive sclerotome arches, it will be seen that there is a stage where there are two vertebral bodies with their arches to every myotome (Fig. 3, A) (J. Graham Kerr⁴), and just as the anterior arches disappear so do the anterior bodies, which probably are represented by the peripheral parts of the intervertebral discs (Fig. 3, B).

In the head the axial skeleton forms the parachordal part of the basis cranii, which consists of the basi-sphenoid and the basi-occipital, the former being the "anterior body," which fuses with the posterior (occipital) instead of disappearing as in other regions (Fig. 3, C). The parachordal tissues show signs of incomplete segmentation in many animals during development, but this takes place before vertebral centra are formed, probably representing a condition similar to that mentioned for the holocephalous fishes, so that such segmentation cannot be homologous with true vertebral segmentation.

The next skeleton to appear during evolution is the *splanchnic skeleton*, and it appears when chordate animals evolve special respiratory organs. The endoderm is the essential tissue of these organs, and it is responsible for the evolution of this skeleton and constitutes its morphological relation. The representatives of this skeleton are the gill-bars in fishes, and the laryngeal, tracheal, and bronchial cartilages in pulmoniferous animals. In all cases this entire skeleton is fixed on to the sclerotome part of the hyoid arch, and in man forms the greater cornua of that bone by means of the hyo-thyroid cartilage (Bardeen⁵). In this way the hyoid bone is formed by the combination of two morphologically different skeletons.

The last of the skeletons to appear is the *facial skeleton*. It is evolved in connexion with the organs of special sense in the form of the capsules of these organs, which combine with the axial and sclerotome skeletons to form the chondrocranium of anatomy. Later, a supplement appears in the form of membrane bone which supports the whole face. It combines with the occipital arch, replaces the trabeculae and Meckel's cartilages except for the malleus, applies itself to the basi-sphenoid as the pre-sphenoid and also to its own sense organ capsules. The existence of this skeleton has been determined by the ectoderm in the form of sense organ, brain, teeth, and general skin covering, and as none of these structures is segmented, neither is the skeleton which supports them.

These few remarks will suffice to show the existence and the difference of the four skeletons in the head, and the importance of this difference may be well demonstrated by referring to the morphological constitution of the anatomical series of arches represented by the mandible, the hyoid arch, and the thyroid and subsequent arches. These are supposed to be an homologous series of branchial arches, but the conditions of their origin upset this supposition. The mandible belongs to the facial skeleton which was determined by the ectoderm, the hyoid arch (sclerotome part) was determined by metamerically segmented mesoderm, and the thyroid and subsequent arches were determined by the endoderm. These arches, since they differ in their origin, cannot be homologous structures.

THE MUSCLES OF THE HEAD SEGMENT.

The Myotome.

The segmented mesoderm or myotome of the head segment has a history unlike that of any other myotome in the body, and its behaviour is unusual in that it gives rise to no muscles except in cyclostome fishes (Agar⁶), but after forming its sclerotome skeleton it disappears. We can only find the explanation of this by investigating the history of mesoderm. Briefly, it is as follows: When mesoderm first made its appearance its somatic part had to segment itself in order to make use of the segmented hydrostatic skeleton. The purpose of this was primarily to effect locomotion. Locomotion was, and is, accomplished in such animals by moving whole segments of the body relatively to each other. This function of moving whole segments becomes so specialized that even in the development of higher animals, myotomes only give rise to muscles which pass between the limits of single segments—for example, interspinales, intertransversales, intercostales, etc. (Lewis⁷).

In the case of the head segment the myotome is formed long before any modification can take place in this segment, and as all cephalic modifications are features of the Craniata they are acquired long after myotomes. We have seen that the segmental limits or sclerotomes of this segment become fixed

to the basis cranii (the mandibular and hyoid joints being formed secondarily), so that the function of the myotome—namely, that of moving the sclerotomes of this segment—no longer exists. There is therefore nothing for this specialized myotomic rudiment to do now but to adapt itself to the new conditions and functions of this segment or to disappear.

The high degree of specialization possessed by a myotome narrows the limits of its adaptability, and the extent of the adaptability of the cephalic myotome is seen in cyclostome fishes where it forms some head muscles (Agar²), but in all other forms the myotome fails even to do this, and after forming its sclerotome skeleton it disappears. In the Elasmobranchs it is a disappearing mass of condensed mesoderm known as the "fourth" myotome of van Wijhe. In *Lepidosiren*, Agar describes a single condensed mass of myotomic mesoderm which gradually resolves into loose unsegmented mesoderm

FIG. 4.—Diagram of section of head mesoderm of *Lepidosiren* embryo (after Agar), showing the dense myotomic mesoderm which extends from behind the auditory region forwards to the optic region. It is in the process of breaking up into loose mesenchyme.

(Fig. 4). It extends from behind the auditory region forwards to the optic region, thus corresponding with the sclerotogenous tissue described by Bardeen for man, in whom also there is only continuous mesoderm prior to the formation of pre-muscle masses (Lewis⁶).

The Somatopleure.

The failure of the cephalic myotome to muscularize the highly modified head segment with all its new organs is compensated for by the less specialized unsegmented mesoderm of this region—mesoderm without any history of ancient specialization. This mesoderm gives rise to all the muscles of the head. The particular source of this mesoderm in the lower animals—Elasmobranchs for instance—is the dorsal wall of the pericardial cavity which is called the splanchnocoel. Mesodermic stalked buds arise from this and form the special muscles required by the various organs.

The first bud quickly becomes separated from the splanchnocoel, and from it arise the four muscles of the eye innervated by the oculomotor nerve. The second gives rise to the superior oblique muscle, while its stalk forms the masticatory muscles. The third bud forms the external rectus, and its stalk gives rise to the facial musculature. Another bud behind these forms branchial muscles, and alongside the notochord a varying number of so-called occipital myotomes are formed, but these largely disappear. As there are no vertebral bodies present at this time, the only structures to which these "myotomes" are apparently related are notochordal rings, and as these fuse to form the basis cranii, so the "myotomes" disappear. Agar describes the last two of this series as helping to form the hypoglossal and coraco-hyoid muscles after fusion.⁵

In mammals the details are very different, as the pre-muscle masses arise *in situ*, but the same occipital "myotomes" are seen and are described as disappearing. They have not been traced to the origin of any particular muscles (Lewis⁶), although their disappearance by fusion is probably the adaptation of these masses necessary for the formation of special muscles. If this is correct, the occipital masses will form the glossal, infrahyoid, sterno-mastoid, and trapezial musculature, also possibly sharing in the formation of the pharynx, as Agar states to be the case in *Protopterus*. These occipital masses have been called "myotomes," but an examination of their origin shows that they cannot be homologous with true myotomes.

The general conclusion is that there are no muscles in the head formed from myotomes. This is in agreement both with evolutionary history and also with embryological investigation (Lewis⁶).

THE SPLANCHNOPLEURE OF THE HEAD SEGMENT.

The Segmental Blood Vessels.

The splanchnopleure of the head segment is quite as evident as the somatopleure. It forms the musculature of the heart and the anterior of the great vessels, and the musculature of the fore-gut, which includes that of the pharynx and larynx.

The heart has long been regarded morphologically as a cephalic viscus, so that it is not necessary to say more about it here. What is of more importance at present is the aorta which gives off the segmental arteries to the various segments. The caudal displacement of the heart in evolution and in development has led to the formation of a ventral aorta which communicates with the dorsal aorta by a series of aortic arches which pass in relation to gill-pouches. These arches are repeated in branchiometric order, and they are of great physiological importance: they have no metameric segmental significance, as somatic segmental arteries are present in addition to branchial arterial arches. With the change to pulmonary breathing, these arches are made use of to effect the changes in arterial redistribution. Some arches disappear and others persist, and it so happens that since all aortic blood is equally oxygenated, the internal carotid artery is part of the dorsal aorta, while the external carotid is now part of the ventral aorta and is joined to the internal by the persistent third arch. This is the embryological means to the morphological end, which is constant in that the common carotid artery is constituted the segmental artery of the head segment.

A segmental artery is an artery arising from that portion of a non-segmental arterial trunk which traverses the metameric segment. It is distributed to the structures within that segment and, in addition, supplies branches to structures beyond the segmental limits, forming anastomoses. The segmental artery is repeated serially in every unmodified segment of the body. The segmental artery to the head segment is the common carotid. It arises from the non-segmental aorta and passes to the head segment, presenting the same three sets of branches that are found in every segmental artery. We may call these—(1) the somatic carotid artery, (2) the splanchnic carotid artery, and (3) the spinal carotid artery.

The somatic carotid artery is represented in man by the external carotid and its branches, with the exception of the superior thyroid, ascending pharyngeal and other splanchnic branches. These branches are differentiated and specialized in keeping with the size and number of the parts of the somatic part of the head segment. The branches anastomose with each other and with somatic branches of vessels posterior to the carotid—subclavian and intercostal.

The splanchnic or visceral carotid artery is represented by the superior thyroid and ascending pharyngeal branches in man. These supply gut structures belonging to the head segment, and these arteries anastomose with splanchnic branches of other aortic vessels.

The spinal carotid artery is represented by the internal carotid artery itself. This is a branch of the common carotid artery which gives off no branches until it reaches the interior of the cranium, where it supplies the brain and its extensions, optic and olfactory. It passes into the skull through the intervertebral foramen (Fig. 2, C), breaking up there into branches like the medullary branch of any spinal artery. It effects anastomoses in the same way with the vessels of the opposite side and with those behind, forming the circle of Willis. The internal carotid is larger than any other spinal artery because it has a much larger amount of tissue to supply, and it is only in man that it is so very large in comparison with the combined somatic and splanchnic branches. The spinal artery of the next segment is the terminal part of the vertebral artery, which is formed indirectly by the hypoglossus artery of early development. Spinal arteries are most constant in size and arrangement, and for this reason the internal carotid artery is a very reliable morphological and anatomical indicator of its segment.

The vein of the head segment is represented by the jugular system, of which the tributaries correspond closely with those of the artery, and it presents the same morphological relations.

The Gut Derivatives.

When speaking of the conditions of metameric segmentation and of its definition, it was pointed out that the condition arose as the result of the segmented condition of the hydrostatic skeleton, and that it only affected the somatic mesoderm forming the myotomes and their sclerotome skeleton. Neither the ectoderm, nor the endoderm, nor the mesoderm immediately related to either ever become segmented themselves, but, by being related to the segments of mesoderm more or less closely, the vessels and nerves supplying these unsegmented tissues are arranged more or less segmentally. This arrangement, in its more primitive condition, has led to the idea that gut and skin have some close relation to segmentation. There is, however, little morphological relationship between segmented and unsegmented structures. They are only anatomically related by nerves and blood vessels. This being the case unsegmented tissues do not necessarily observe segmental limitations, and the gut is an excellent example of such a condition.

The gut related to the head segment by the vagus nerve varies in different animals, but in man it includes all the parts of the fore-gut—that is, pharynx, respiratory system, and digestive tract with its appendages down to the second part of the duodenum. When this extent of gut is related to the developing vagus nerve, the relation with the head segment is quite evident. The stomach later acquires its sympathetic nerve supply during its descent into the abdomen (Lewis).

The behaviour of the coeliac axis artery during development also indicates the complete want of segmental form in the gut. This vessel arises opposite the seventh cervical segmental artery and descends to below the twelfth dorsal segment along with the stomach (Evans⁸). No segmental artery, so long as it is a segmental artery, can move about in this way.

In some malformations of the acardiac type there is, corresponding with the absence of the heart, absence of the entire head segment, the thoracic viscera, and of the gut down to the middle of the duodenum—that is, the whole fore-gut.⁹

It is apparent, then, that the whole fore-gut is related to the head segment. It has, like all the other embryological layers in the head region, become very extensive and enormously specialized, and it no longer observes the morphological limitations of its associated segment.

The Ectoderm Related to the Head Segment.

As the parts related to the head segment have become so extensive and specialized, it is to be expected that the ectoderm will present a similar condition. So far is this the case that the ectoderm forms three categories of structures—namely, the central nervous system, the organs of special sense, and the general skin covering of the head and face. This includes the lining of the oral, nasal, and conjunctival cavities, and the exterior of the gill mucous membrane in gill-breathing animals. There is an intimate morphological relationship between these three groups of structures, but as it has no immediate bearing upon the present considerations we shall pass straight on to the nerve of the head segment.

The definition of a segmental nerve is as follows: A segmental nerve is a nerve which contains fibres for innervating all the epiblastic, mesoblastic, and hypoblastic structures related to one coelomic cavity, and it is serially repeated in every metameric segment in the body. In vertebrates segmental nerves usually observe the segmental limits and leave the neural axis by passing between adjacent neural arches which alone form the intervertebral foramina. As many of the cranial nerves have been looked upon as segmental nerves themselves we shall examine the various neural foramina and see how far they agree with the morphological neural or intervertebral foramen.

In the human skull the olfactory nerve does not leave the cranial cavity at all, but the optic nerve does so through a foramen in the orbital-sphenoid. As both of these nerves are extensions of the neural tube they are not homologous with the other nerves. The oculomotor, trochlear, abducent, and ophthalmic divisions of the trigeminal nerve all pass through the superior orbital fissure of the sphenoid, which is facial skeleton. The next two foramina are also in the sphenoid and transmit the maxillary and mandibular divisions of the trigeminal nerve. The chorda tympani passes through the petro-tympanic fissure, which is an interval between the sphenoid and the otic capsule, which are both parts of the facial skeleton. The facial and auditory

nerves both enter the petrous bone, which is part of the facial skeleton. The glosso-pharyngeal, vagus, and spinal accessory leave by the jugular foramen, which is bounded by the petrous bone of the facial skeleton in front and by the occipital of the sclerotome skeleton behind, while the hypoglossal nerve passes through the occipital in its own canal.

It will be seen that none of these foramina is a true intervertebral foramen, as none is bounded before and behind by a sclerotome arch. The only segmental neural foramen is the morphological gap between the site of the trabeculae (pituitary fossa) (Fig. 2, C) and the occipital arch. This gap is now filled up by part of the facial skeleton, which is perforated for the passage of nerves and blood vessels. This is in complete agreement with the development of these foramina, which differ considerably from that of intervertebral foramina.

If it be remembered that the somatic muscles of the head are all formed from unsegmented somatopleure, and that there is now no myotome, it will be realized that all the somatic motor nerves are of the same kind, and that they are all homologous with the spino-occipital nerves of Fürbringer, which is the name given to a variable group of motor nerves occurring anatomically between the vagus and the first spinal nerve. Morphologically this group of somatopleural nerves of the head region is represented by the oculomotor, trochlear, motor part of the trigeminal abducent, and facial nerves. These are all motor nerves to the muscles related to the facial skeleton. The corresponding nerves of the metameric part of the head segment include the hypoglossal, spinal part of the spinal accessory, and those cervical branches to the infrahyoid muscles, trapezius, and sterno mastoid. Here is another instance of the disregard for segmental limitations.

The sensory somatic nerves are the trigeminal and auditory to the facial ectoderm. The auditory nerve is originally a differentiated and specialized branch of the fifth nerve (Owen¹⁰). In the metameric part of the head segment somatic sensory ganglia are developed on the roots of the spinal accessory and the hypoglossal, but these disappear, and are probably related to the ectoderm of the gill-pouches which are obliterated by the closure of the cervical sinus.

Of the splanchnic nerves there are none in the facial part of the nerve, as there is no gut in the face. But in the head segment there are three specialized branches of the viscera nerve—the glossopharyngeal, vagus, and the cerebral part of the accessory nerve.

Such is the constitution of the nerve of the head segment and, so far as the nerve can be called segmental, it is only by looking upon these various nerves as the differentiated and specialized branches of a single mixed nerve that we can account for the endless variety in the details of their distribution and relations that is seen among vertebrates.

This brief statement of the "single segment" point of view of vertebrate head morphology is all that can be given here, but sufficient has been said to show what extreme specialization may be reached by a primitive structure subject to evolution. A simple, almost unmodified, metameric segment is the morphological basis of the vertebrate head, and the mesodermic segment has given place to structures more suitable and efficient for the changed conditions. Little remains now of the primitive segment. The one structure pointing to the segmented condition is the internal carotid artery, which, through all the evolution of segmented chordate animals, has maintained its segmental independence as the spinal artery of the head segment.

(Since the present paper the presence and behaviour of the nerve in the chick. The reconstructions and sections showing the cephalic myotome were exhibited in the Section of Anatomy at the Annual Meeting. The head mesoderm of the mamma

SOME OBSERVATIONS ON THE SHAPE OF THE
PALATE IN CHILDREN.

BY

W. KERR CONNELL, M.B., Ch.B.,

Glasgow.

THE following remarks are based on a study of over a thousand dental impressions, or rather "bites," obtained from the mouths of Glasgow board school children of ages ranging from 4 to 14 years. The method by which these "bites" were obtained and the manner in which they were measured were as follows:

A layer of plasticine (approximately 2 mm. thick) was spread evenly on oblong cards, about 1 mm. thick, and of suitable size and shape. The school children were asked to bite on these cards, thus leaving impressions of their teeth. The age and sex of the child were in each case noted on the back of its card. Each bite so obtained was placed beneath thin square-millimetre paper, previously rendered completely transparent by moistening with cedar-wood oil. In this way it was found possible to make accurate tracings of the various "bites," so that they could be easily and correctly measured.

These measurements are not yet completed—indeed, it will be months before they can be finished—so that I need not refer to them in detail. Such figures as I may allude to in connexion with the growth of the palate, the variations in its shape, and the times of eruption of the permanent teeth, have been culled from a much smaller series of "bites"—a sort of "trial series" which I worked out some months ago.

The reasons for collecting a series of "bites" were: (a) To learn something about the chief variations in shape of the palate; also the relative incidence of these shapes at different ages and in the two sexes. In this connexion the objections may be made that a "bite" gives no true indication of the actual shape of the palate, and also that it tells us nothing about the height of the palate. The latter objection is unanswerable, but the former is open to debate. (b) To see what variations in shape (if any) may be caused by certain diseases—for example, adenoids. (c) To gain information, if possible, about the growth of the palate. (d) To obtain statistics as to the periods of eruption of certain of the permanent teeth. (e) To learn definitely whether or not the size of the palate bears any relation to the general size and development of the individual. These five points may now be dealt with serially.

(a) Nine definite and distinct types of palate were found to exist, and the following table shows their relative incidence:

(1) Oval*	57.18 per cent.
(2) Wide oval	11.59 "
(3) Pointed	7.81 "
(4) Narrow oval	5.55 "
(5) Square oval	4.19 "
(6) Square	4.29 "
(7) Asymmetrical... ..	4.01 "
(8) Bell—Type B	2.27 "
(9) Bell—Type A	1.51 "

*By far the commonest type, in both sexes and at all ages.

It may be observed that "narrow ovals" are much commoner in girls than in boys, and that "squares" are commoner in boys than in girls. The remaining shapes occur with approximately equal frequency in the two sexes.

(b) With the kind assistance of Dr. Syme, I was able to obtain a small series of 45 "bites" from the mouths of patients at the Western Infirmary suffering from pronounced adenoids. Judging by the statements made in most surgical textbooks, one would have expected to find a preponderance of small, narrow, pointed impressions. It was therefore decidedly surprising to discover, in this series of "bites," a striking absence of such characteristics. In fact, little or no deviation from the normal could be seen. The majority of the "bites" showed the ordinary "oval" features.

(c) I cannot say much about the growth of the palate until my statistics are completed; but one rather suggestive feature is shown (from observations on the original small series of "bites")—namely, a slight fall in the intercanine measurement between the 11th and 14th years. This seems to indicate an actual absorption of bone in this situation.

(d) When speaking of "eruption" in connexion with those tooth impressions I mean, of course, an eruption of sufficient degree to register a mark on the plasticine: the actual eruption must precede this. Permanent incisors and canines do not leave sufficiently characteristic impressions to enable them to be distinguished from the corresponding temporary teeth, but all the other teeth leave markings which are quite

unmistakable. The results of studying my original series of "bites" from this point of view show that, while eruption occurs earlier in the male, it is more rapidly completed in the female.

(e) Early in the course of investigations it became quite clearly apparent that the size of the plate bears absolutely no relation to the general size and development of the individual child.

In conclusion, it may be stated that my chief purpose in publishing these results in their incomplete and unfinished form has been to bring forward the method adopted. It seems to me to be the only practicable method of studying the palate in children, for any elaborate system—such as the taking of plaster-of-Paris casts—is quite out of the question, and would lead to a luo and entery on the part of the children's parents.

A MESENTERIC CYST OF JEJUNAL ORIGIN COM-
PLICATED BY RETROJEJUNAL POSITION
OF THE TRANSVERSE COLON.

BY

JOHN I. HUNTER, M.B., Ch.M.,

Associate Professor of Anatomy, University of Sydney.

THE specimen described in the following paper is of interest on account of the clear connexion to be traced between fatal pathological conditions of the alimentary tract of a newborn child and their developmental origin. It consists of the viscera, with their peritoneal attachments, of a child who died seven days after birth.

cc threatened
time. The
pr. lly was ex-
perienced in extracting the after-coming head. On examination the child exhibited great abdominal distension, particularly of the upper part of the abdomen; there was also facial paralysis and talipes of the right foot. The child took its food fairly well and its bowels were kept going with enemata. It appeared to be in constant pain. It did not thrive, and died at the end of seven days.

Post-mortem examination revealed a considerable quantity of free fluid in the peritoneal cavity; two large cyst-like growths were found in the mesentery, and the transverse colon was observed to be absent from its usual position and to be behind the small intestine and the attachment of the mesentery. On account of these features the abdominal contents were removed in order to be submitted for further examination. The patient was under the care of Dr. R. N. Gibson, who transmitted the specimen to the Anatomy Department, University of Sydney; and his resident medical officer, Dr. Sinclair, of the Crown Street Women's Hospital, Sydney, performed the *post-mortem* examination and supplied the above notes. When the alimentary tract was examined the duodenum was found to be somewhat dilated (1.5 cm. in diameter). The distended tube had its usual U-shaped bend, but its terminal limb was in contact with the greater curvature of the stomach and first part of the duodenum, to which it was bound by fine adhesions (Fig. 1). The jejunum for 10 cm. beyond the duodeno-jejunal flexure was still further distended (2.5 cm. in diameter); beyond this point it commenced a circular course from right to left, along the edge of two well-marked cystic swellings which were lying along its mesenteric border and between the two layers of mesentery (Fig. 1). The jejunum was stretched transversely upon these swellings so that its lumen was slit-like in cross-section. The swellings on external examination appeared to be two separate oval cysts lying side by side, but on opening their walls they were found to be two loculi of a single cyst, communicating with one another at the intestinal border of the mesentery by an opening 1 cm. in diameter (Fig. 1, n).

The wall of the cyst is on the average 3 mm. in thickness and contains what is apparently a considerable sheet of muscle tissue. The fluid within the cyst was dark brown in colour, apparently revealing the occurrence of haemorrhage some time previously. Each loculus is of considerable size, that on the right measuring 55 by 43 mm. and that on the left 68 by 41 mm. Each loculus is somewhat larger than the specimens mentioned by Keith.¹ One of these (No. 1952 A, St. Bartholomew's Hospital Pathological Museum) measured 45 by 25 mm., and the second specimen (No. 2523, Royal College of Surgeons, England, Museum) was 25 mm. in diameter. These represent two of the three cases of cysts in connexion with the small intestine, which he discussed in a

review of the 156 cases of diverticula of the alimentary canal which are to be found in museum collections in London. Professor Koehl is of the opinion that these cysts owe their origin to diverticula of the small intestine which have become

closed off by constriction of the neck adjacent to the point of communication with the bowel. Moynihan, in a recent lecture, supported a similar view.

The present specimen is of interest in connexion with the etiology of the mesenteric cyst because its wall contains all the elements found in the wall of the intestine; and yet, as a careful dissection showed, no communication existed at the time of examination with the intestine. The original structure from which the cyst has been formed is exhibited with clearness at the most proximal part of the swelling (Fig. 1, A). Here the cyst is prolonged into a blind tubular

FIG. 1.—The specimen viewed from the front. The jejunum and ileum are represented as having been partially removed to display the cyst. The transverse colon is hidden behind the first part of the jejunum.

extremity 13 mm. in diameter, which lies parallel to the adjacent jejunum. The lumen of this tube is comparatively small (4 mm. in diameter), and its wall is predominantly muscular. A portion of this blind extremity of the swelling was submitted for examination to Professor D. A. Welsh, Pathology Department, University of Sydney, whose report is included here.

"The lumen of the hollow tube contains a mass of leucocytes, mixed with fibrin and recently extravasated red blood cells. The leucocytes form the main portion of this mass, and the majority appear to be neutrophils with polymorphous nuclei, indicating some persistent irritation.

"The lumen of the tube is lined by a thick layer of a highly granular tissue. Next the lumen the granulation is very dense, and the cells, which are very large and voluminous, tend to lose their nuclear structure, becoming fused to form a continuous cytoplasmic mass, which is relatively non-vascular.

"Beyond this zone the granulation tissue is more cellular with numerous small cells, well-staining nuclei, and abundant small blood vessels with well-defined endothelium and blood content. In the deeper zone fairly numerous isolated cells of the granulation tissue appear to be undergoing necrosis. One or two of them fuse together, stain deeply with haematoxylin instead of with eosin, and ultimately become unrecognizable as cells, resembling rather spicules of some foreign matter embedded in the tissue. These necrotic cells may be in process of calcification, and may represent the starting point of larger calcareous masses which are to be found in the wall of the cystic portion of the tumour.

"There is no trace of an epithelial lining to the lumen, but that fact does not necessarily mean that epithelium has never been present there. It may have disappeared under pressure or under the long-continued inflammatory process.

"The muscular coat represents roughly three-fifths of the total thickness of the tube, about one-fifth being the granulation tissue of the inner coat and about one-fifth the thickened subserous coat.

"The transverse section of the tube cuts many of the muscle bundles in transverse and oblique section, especially in the inner two-thirds of the muscular coat, indicating that the bundles there tend to run longitudinally along the wall of the tube. But the outer third of the muscular coat is definitely and uniformly disposed in a circular manner around the tube.

"All these muscular bundles are irregularly, but on the whole widely, separated by a great inflammatory increase of the inter-muscular connective tissue. In places this increase is highly cellular; in other places it has undergone a great expansion to a less vascular and highly myxomatous tissue.

"External to the muscular coat the outer fifth of the wall of the tube is made up of a relatively enormous thickening of the subserosa. This thickening has a loose fibro-cellular structure with numerous and relatively large thick-walled blood vessels, and a few nerve fibres.

"There is no evidence of any new growth in the sense of neoplasia. The tumour appears to consist of a greatly inflamed structure, suggesting a portion of altered bowel wall, possibly a diverticulum that has now been cut off from the bowel from which it originally started."

There appears to be no reasonable doubt that the cyst in this specimen originated as an enteric diverticulum. Lewis and Thynp² have shown that intestinal diverticula occur regularly in embryos of the pig, rabbit, and man, and that

their presence has been noted in the cat and sheep. The diverticula are more numerous in the older embryos studied, and occur especially in the distal part of the small intestine. The human material studied by these authors showed—

"That solid knob-like diverticula of the intestine may occur before the formation of the dorsal pancreas, but that older embryos from 7.5 to 10 mm. may be without them. An embryo of 13.6 mm. showed one prominent duodenal pocket, with indications of 12 others along the small intestine. At 23 mm. 33 pockets were counted, and in an older embryo there were 48. In these, and in an embryo of 32 mm., no diverticula were found along the large intestine and vermiform appendix" (p. 513).

They believe that these diverticula degenerate, sometimes becoming detached to form cysts. In a 20 mm. pig embryo, which showed twelve intestinal diverticula, they found a thin-walled epithelial cyst with a few rounded outpocketings just outside the muscularis of the duodenum a short distance from the pancreas, together with a solid cylindrical outgrowth of the intestine which extended to the muscularis. This they interpret as the original stalk of the cyst, which has been carried along and its direction altered by subsequent growth of the intestine. Undoubtedly the present case is a clear example of such a cystic degeneration of a detached diverticulum of the small intestine. According to the current classification³ the diverticulum falls into the congenital class, being characterized by the possession, in the first place at all events, of all three coats of the small intestine. Acquired diverticula have been defined as consisting of mucosa and serosa only (false diverticula), but they may exhibit all three coats (true diverticula).

The second important abnormality of the alimentary tract, exhibited by the specimen is the position occupied by the transverse colon, which was detected at the *post-mortem* examination. The ascending colon is short, and the right colic flexure bends round the jejunum to lie behind the root of the mesentery and that part of the jejunum proximal to the commencement of the cyst. The ascending and transverse colon are both provided with a mesocolon, which is attached along its fixed edge to the posterior wall of the adjacent jejunum and the root of the mesentery. The mesocolon and mesentery are continuous at the ileo-caecal junction. The transverse colon passes into the left colic flexure and descending colon, but these parts have been denuded of peritoneum in the process of removal.

The question which must be decided is whether the two abnormal conditions of the alimentary canal are causally related to one another. The retrojejunal position of the transverse colon may be explained by supposing that the rotation of the intestine was from right to left as usual, but that the transverse colon in the process became folded behind the mesentery and the upper part of the jejunum, which is attached by it to the posterior abdominal wall (Fig. 2). How

FIG. 2.—A diagram representing the effect of malrotation of the intestine to explain the retrojejunal position of the transverse colon.

could such an abnormal rotation occur, and has it been brought about by the presence of a diverticulum of the intestine which had undergone cystic dilatation at the time rotation occurred? Frazer and Robbins have recently reviewed the problem of the development of the intestine and the manner in which the final relationships of its various parts are assumed.⁴ They believe that it is impossible for the umbilical coils to return *en masse*, and that the alteration in position is accomplished by a movement of each limb of the intestinal loop, in turn, the proximal limb first and the distal limb next.⁵ This is due to the shortness of the umbilical colon compared with the peritoneal attachment of

the small intestine, their belief being that the colic angle beyond the distal limb is held in position by a "retention band" which blends with the mesenchyme surrounding the superior mesenteric artery; this tissue grows less rapidly than the caudal end of the body.

The immediate result of the return of the colon after the proximal intestinal limb is that it lies in front of the coils of small intestine, with the caecum wedged in from behind between these coils and the liver, the caecum being the last to return. That is to say, at about the tenth week of development the return of the umbilical coils and the rotation of the gut occur as parts of one process. Now, if we suppose that in the specimen being described the distal limb returned first and then the proximal limb afterwards, the result found at birth would be produced. For, in this case, the last portion to return (the small intestine) would lie in front of the transverse colon, which would have already taken up its position. Such a roversion of the order of return leading to malrotation could conceivably occur if the proximal limb were anchored in position, and I suggest that such an anchorage may have been produced by the presence of a cystic diverticulum of the small intestine. In this case we must suppose that the pathological development of the crotic diverticulum must have occurred before the tenth week, so that the return of the distal limb was more easily accomplished than the proximal. After its return to the abdomen the cyst enlarged sufficiently to interfere with the normal peristalsis of the neighbouring bowel, so leading to partial obstruction with consequent malnutrition of the child and ultimately to death.

In conclusion it is a pleasure to express my thanks to Dr. R. N. Gibson and Dr. Sinclair, who furnished the specimen, and to Professor D. A. Wolsh, who provided the pathological report, which has been included with the foregoing description, and on which some of the conclusions have been based.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

TWO CASES OF ACUTE LYMPHATIC LEUKAEMIA.

The following account of two cases of acute lymphatic leukaemia in infants seems of sufficient interest to warrant publication.

CASE I.

The first case was that of a female aged 3 years, who had been healthy until three weeks before admission, when her parents noticed that she was paler than usual. She was admitted on December 30th, 1921, and died the same night with symptoms of cardiac failure.

Post-mortem Examination.—Cadaver pale. Purpuric spots on legs and chest. No superficial glandular enlargement. Purpuric spots on pericardium and pleurae. Heart pale and flabby. Thymus normal. No enlargement of mediastinal glands. Mesenteric glands markedly enlarged. Spleen slightly enlarged. Liver and kidneys large and pale. Bone marrow of femur pink in colour.

Blood Film.—A film was taken on admission and showed lymphocytes 89 per cent., myelocytes 5 per cent., polymorphonuclears 3 per cent., transitionals 1 per cent., large mononuclears 2 per cent. The small lymphocytes predominated—76 per cent. to 24 per cent. of the large variety. Anisocytosis was marked and normoblasts and megaloblasts frequent.

Histology.—Sections showed the usual lymphatic infiltration in all the organs. The bone marrow of the femur appears devoid of fat and consisted chiefly of lymphocytes and red corpuscles.

CASE II.

The second case was that of a male aged 2½ years. A month before admission the cervical lymph glands were noticed to be enlarged. The child was admitted on August 1st, 1922, with acute angina, and died the same night.

Post-mortem Examination.—All the lymphatic tissues were enlarged. Superficial glands of neck, axillae, and groins, tonsils, thymus, mediastinal and mesenteric glands very much enlarged. Peyer's patches prominent. Liver and kidneys enlarged and pale. Spleen very little enlarged. Purpuric spots on pericardium.

Blood Film.—This showed lymphocytes 99 per cent., of which the small variety numbered 82 per cent. and the large 17 per cent.

Sections.—All the organs showed lymphocytic infiltration.

The points of interest are: (1) the ages—3 and 2½ years; (2) the fact that one patient was a female; (3) in one case the

lymphatic tissue enlargement was confined entirely to the abdominal glands, while in the other all the lymph glands in the body were involved.

W. E. COOKE, M.D., F.R.C.P.E., D.P.H.,
Hon. Pathologist and Bacteriologist, Royal Albert Edward
Infirmary, Wigan.

CASE OF SPLENO-MEDULLARY LEUKAEMIA.

The following case is of interest on account of the acute onset and of the marked improvement in the general condition which followed treatment by x rays, the removal of a source of sepsis; the use of an autogenous vaccine, and the exhibition of arsenic internally.

A married woman, aged 33, was admitted to the Leicester Royal Infirmary on March 23rd, 1922. She gave a history of ill health for a period of six weeks, complaining of weakness, giddiness, headache, and vomiting, with severe pain in the left hypochondrium. She had been losing flesh for three weeks.

On admission she was thin and pale, with a dry, furred tongue, had pyorrhoea, and a spleen enlarged to two inches below the umbilicus and one inch beyond the mid-line (Fig. 1, a). There was no liver or glandular enlargement and no tenderness of the long bones. The optic discs were normal. Her pulse was small and rapid, and she was very ill indeed. On March 23rd a blood count showed: red cells, 3,333,000; leucocytes, 53,125; haemoglobin, 40 per cent. Smears were crowded with myelocytes and normoblasts. A small faintly Gram-positive diplococcus was obtained from a blood culture, but unfortunately it was found impossible to subculture the organism. The pathologist remarked that the blood picture was typical of spleno-medullary leukaemia. At that time the temperature ranged between 99° and 103° (Fig. 2, a), with an evening rise, and the pulse was 120 to 140.

The first x-ray exposure was given on April 6th. It consisted of one pastillo dose to the spleen and long bones. This was repeated twice a week. During the first week the temperature fell to normal in the morning and never rose above 100° in the evening

FIG. 1.—Size of spleen—(a) on admission, (b) on discharge.

FIG. 2.—Portions of temperature chart showing character of the variations under treatment.

(Fig. 2, b). On April 19th her lower incisors, canines, and upper and lower molars and premolars were removed under nitrous oxide. Cultures from tooth fangs contained streptococci, diphtheroid bacilli, and Micrococcus catarrhalis, and an autogenous vaccine was prepared. On April 29th the first dose of vaccine was given; this was repeated every fifth day until eight injections had been given. The temperature became more irregular, but rarely rose above 99° (Fig. 2, c). A slight reaction occasionally followed the injection of the vaccine. On May 5th the blood count was: red cells 3,300,000; leucocytes 23,000; haemoglobin 50 per cent. Myelocytes and one normoblast were found.

From June 2nd the temperature rarely rose above normal (Fig. 2, d) and the pulse was slower though somewhat irregular. During the whole of the time she was in hospital she was taking arsenic by the mouth. From the beginning of the x-ray treatment the spleen steadily diminished in size, and when she left the hospital it could not be felt below the costal margin. The patient was quite well, had no pain nor discomfort, and the blood count on June 21st was: red cells, 3,065,000; leucocytes, 5,625; haemoglobin 50 per cent. Myelocytes were still present but they were extremely few. No other abnormal cells were found.

I wish to thank Dr. Crosby, physician to the Leicester Royal Infirmary, under whose care this case was, for permission to publish these notes.

A. DOROTHY POOCK, M.B., B.S.,
House-Physician, Leicester Royal Infirmary.

Reports of Societies.

MEDICAL SOCIETY OF LONDON.

THE annual general meeting of the Medical Society of London, which inaugurated the 150th session, was held on October 16th. Mr. James Berry vacated the chair in favour of Lord Dawson of Penn, whom he invested with the presidential badge. In a review of the year's work Mr. BERRY mentioned that the Fellowship of the Society now included 625 names, and that the average attendance at the meetings during the past session was forty-seven. A very hearty vote of thanks was accorded to Mr. Berry, and another to Dr. Mitchell Bruce, who is retiring after a long tenure of the treasurership. The balance sheet of the Society reveals a flourishing condition, with a balance of assets over liabilities of £6,640, without including the uncertain value of the library and furniture, which is moderately estimated at £5,000.

Lord Dawson then delivered his presidential address on "Certain developments in medicine," which is printed at page 781. The address was excellently received, but Lord Dawson's departure from precedent in calling for discussion after an address from the chair met with very little response.

Sir HUMPHRY ROLLESTON proposed a vote of thanks to the President for an admirable and fascinating address of the kind which required to be pondered over before it could be adequately discussed. One interesting point which Lord Dawson had raised was the possibility of the gradual change of diseases in their type. Within the lifetime of any one medical man it was difficult to estimate accurately how much change of type in disease there might be. To what extent the wear and tear of London or of American life had altered the character and relative incidence of diseases it was very difficult to decide. The matter was confused also by the fact that the nomenclature of diseases altered as well as, possibly, their characteristics. But from George Cheyne's *The English Malady* (1733) he gathered that neurasthenia, although not then called by that name, was an almost universal disease in the early part of the eighteenth century, and he could not help wondering whether the great importance now attached to nervous diseases was due, not to the new prevalence of those diseases, but to the fact that medical men were better educated and nervous diseases more easily detected. With regard to the psychoanalysts, of whom Lord Dawson had spoken, he thought that Freud's general conception, apart from the special development of it in connexion with sexual matters of which so much had been heard, was one for which they ought to be grateful. It was possible that the principle which Freud had put forward had been directed by some of his followers and also by himself along two special lines. The sexual element, after all, must not be allowed to monopolize the field. The psychoneuroses of the war, for instance, had no sexual element; they had to do with an instinct equally strong—that of self-preservation. Lord Dawson had paid a handsome tribute to Sir James Mackenzie for his work on the early symptoms of disease. In that tribute they would all concur. Sometimes it might be a little difficult to follow what was being done at St. Andrews, but in justice to the institute the fact must be borne in mind that it had undertaken an enormous task, and that years possibly would have to elapse before any particular result was obtained. Another question which Lord Dawson had raised was the need of medical institutions for people of moderate means. With this principle, again, they would all be in agreement, though it was a difficult problem as to how exactly such institutions should be run. He was aware that many different methods had been proposed, but he felt that if he discussed their respective merits he might find himself in the position of the Irishman who, after listening to a rather fervid protest to the effect that one man was as good as another, replied, "Faith, and a good deal better too!"

Sir JOHN BROADBENT, in seconding the vote of thanks to Lord Dawson, said that they were grateful to him because, in spite of all temptations to be a politician, he had remained a medical man.

Dr. LENNOX WAINWRIGHT, commenting upon Lord Dawson's reference to modern hurry and stress, said that this had an important bearing upon the treatment of the mind. Gladstone used to say that change of occupation was rest, but he doubted whether that principle held good to-day in view of

the complication and haste of modern life. Another point was the desirability that the physician should judge how the patient would bear or interpret the knowledge he might impart to him with regard to his condition. Some patients, for example, had the most curious notions with regard to the dangers to be apprehended from micro-organisms. He knew a lady who shrank each doorknob she turned with a handkerchief, believing that it was a mass of microbes. Patients were easily led astray by a physician's warning or counsel, so that they took a graver view than their case justified. The psychology of the patient must be studied. The vote of thanks was accorded by acclamation, and Lord Dawson acknowledged the compliment.

MYOMECTOMY FOR UTERINE FIBROIDS.

A MEETING of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine was held on October 5th, with Dr. T. W. EDEN, President, in the chair, when Dr. ARTHUR E. GILES read a paper on the subject of indications and results of myomectomy for uterine fibroids.

Dr. Giles said that in recent discussions on the treatment of uterine fibroids the alternatives of hysterectomy on the one hand and x-ray and radium treatment on the other had generally been dealt with as though they exhausted the possibilities of treatment. Myomectomy had been almost entirely overlooked. He held the view that in the majority of cases of fibroids requiring surgical treatment hysterectomy was the more suitable and also the more satisfactory operation, and that the scope of myomectomy was restricted to the minority of cases. Hysterectomy needed no justification; it was generally accepted as a sound procedure, surgically and clinically. But myomectomy had to justify itself by its results, and to state reasons why it should be preferred; it had also to acknowledge its limitations and to define the conditions of its suitability. The outstanding claims for myomectomy were, first, that the uterus was preserved for the important function of child-bearing; the second that the patient was spared thereby the mental distress of feeling that an essential part of her womanhood had gone.

In regard to the immediate results, Dr. Giles's figures from the end of 1910 to date were as follows: hysterectomy, 684 cases, 5 deaths—mortality 0.73 per cent.; myomectomy, 107 cases, 1 death—mortality 0.93 per cent. There was, therefore, very little difference in the mortality of the two operations; certainly not enough to make that a deciding factor in the choice of operation. In his work on the after-results of abdominal operation, published in 1910, he was able to give particulars of 40 cases traced out of 51 operated upon; of the later 116 cases he had particulars of 53. He did not attempt to trace the histories of patients who were over 45 years of age at the time of operation. Of 88 cases examined in the earlier and in 79 of the present series the uterus was free from fibroids, and in 9 cases further tumours were found. The inference from this was that the liability to return to fibroids might be represented as 10 per cent. Excluding cases in which the menopause preceded or synchronized with the operation, particulars about the character of menstruation after the operation were obtained in 83 cases; in 67 of these, or 80.7 per cent., the menstrual loss was normal or moderate; the remaining 16 patients suffered from excessive loss. To help in gauging the value of the results it might be stated that in 31 out of 51 cases in the present series at least six years had elapsed between the time of operation and the report on the case. In both series there were fifty women under 45 years of age who had a chance of becoming pregnant, including three who were single at the time of operation and married afterwards. Of these 14, or 28 per cent., became pregnant.

Comparing the advantages of myomectomy with its disadvantages, it might be said that the advantages were represented by the occurrence of pregnancy in 28 per cent. of the women who had the chance of pregnancy and by the satisfaction which patients derived from the consciousness that after the operation they remained "like other women." The disadvantages were the possibility of the return of fibroids which was a 10 per cent. chance, and the possibility of further menstrual trouble, which was a 20 per cent. chance. The risk of a second operation being necessary was not as great as 10 per cent.; hysterectomy had been required in only five cases out of the total 167—that was, in just 3 per cent. The younger the patient the greater should be the effort to save the uterus, and his opinion was that, broadly, myomectomy was the operation of choice in women up to the age of 40. In single women the indication was not so great as it was in

married woman, especially after the age of 30. When a tumour was solitary and pedunculated and not associated with excessive bleeding a myomectomy might properly be done, whatever the age of the patient and the chances of pregnancy might be. Even an interstitial tumour unassociated with haemorrhage might be enucleated. After the age of 40 to 45 he considered that hysterectomy should be the rule, especially when there were multiple fibroids and when there were excessive haemorrhages. Whatever the position or number of the tumours, if myomectomy was going to leave a battered and useless organ hysterectomy should be done. Cervix fibroids almost invariably called for hysterectomy, though he had occasionally done a myomectomy even in these cases. The mere number of the tumours did not matter so long as a good and serviceable uterus was left. When a patient suffered from excessive haemorrhage and was seriously drained thereby, hysterectomy should be the rule.

Fibroids associated with pregnancy did not necessarily call for surgical treatment. When they were causing no symptoms and did not seem likely to interfere with labour it was best to leave them alone, always provided that the patient could be kept under observation so that operation could be undertaken if urgent symptoms arose. Myomectomy during pregnancy was indicated in three groups of conditions: first, when the tumour or tumours appeared to be increasing rapidly in size; second, when the patient was in, pressure symptoms, or indications of changes in the tumours; third, when the position of the fibroids made it probable that labour would be obstructed, in which case myomectomy was done for the purpose of avoiding the necessity for Caesarean section and of allowing the confinement to take place naturally. In all he had had thirteen cases of myomectomy during pregnancy. The period of gestation ranged from a few days to six months. The results of the last two cases he had been unable to trace; in the remaining eleven the pregnancy was not interfered with, and all of them went to full term, except one whose labour came on at 7½ months, but the child was alive and survived. Myomectomy during pregnancy was evidently a most satisfactory operation.

Scope and Technique of Myomectomy.

Mr. Victor Bonney read a paper on the scope and technique of myomectomy. He said that myomectomy in principle fulfilled a higher surgical ideal than hysterectomy. He recorded a series of 100 consecutive myomectomies to show that within wide limits neither the number nor position of the tumours in the uterus, nor the presence of degeneration, nor the accompaniment of menorrhagia or pregnancy, was a bar to successful performance of the operation. The largest number of fibroids that he had removed from the uteri in a single case was thirty, but he did not regard this as the limit of possibility. Anterior tumours were more favourably placed for enucleation than posterior tumours, because they could all be got out through an anterior incision, but many posterior tumours could also be removed by the same route. Malignancy and sepsis of course barred the operation, whilst naevoid degeneration made the operation more formidable; but with these exceptions degeneration of the tumour, or tumours, had no bearing. In regard to the technique of the operation, Alexander of Liverpool laid down the right principle twenty-four years ago—namely, an anterior incision in the uterus, and if possible all the tumours removed through that one incision. The speaker then proceeded to show by diagrams the manner in which the enucleation cavities could be closed by suture. When fibroids were complicated by pregnancy and an operation was required, myomectomy should be combined with Caesarean section if the child was viable. If the child was not viable the ideal procedure was to remove the tumours and leave the pregnancy *in situ*; where many tumours were present, however, this was impossible, and the pregnancy should be removed through the same incision as the fibroids. He had two deaths in his series of 100 cases; all the other patients had done well, and none of them had returned to him with new fibroids or return of the bleeding. Five patients had become pregnant subsequent to the operation; of these, one and fourteen, another eight, and another five, fibroids removed, and two had one fibroid each removed. Four of these patients delivered themselves naturally. The remaining one was delivered by Caesarean section, but the condition of the uterus at this second operation showed it to have been un-

necessary. He hoped that in the future it will be common knowledge that fibroids do not, as a rule, necessitate hysterectomy, and that if the possessors of these tumours will only submit themselves to early surgical treatment their wombs need never be removed.

The President cordially agreed with the ideals expressed by Mr. Bonney. He had always thought and always taught that the removal of the uterus was surgically a very crude procedure to adopt in order to deal with a benign growth. The surgically ideal procedure must be to remove the neoplasm and conserve the organ in which it grew. His own practice had been to adopt myomectomy much more freely than Mr. Bonney seemed to think was the case with most gynaecologists, and he welcomed the efforts which were being made by the authors to call attention to its advantages.

Professor Briggs had long ago recognized the increasing sphere of enucleation in the progressively earlier treatment of uterine fibroids; he appreciated the illustrative modern reports in the papers just read. Allusion had been made to Dr. Alexander's work in Liverpool prior to 1898. At that time Professor Briggs by many laboratory tests of enucleation had convinced himself that the older fibroid growths, degenerated and adherent to their capsules, were physically unsuitable for enucleation. In his opinion enucleation was at its best when the scalpel could be thrust directly into the substance of the thyroid, cutting it into halves or less, reducing its bulk and providing for the insertion of an appropriately strong sharp hook for its extraction with the minimum surgical interference with its capsular connections. Fantastic uterine tunnelling was unnecessary. It had to be borne in mind that after the most thorough uterine palpation a fibroid growth might remain.

Dr. HENRY SPENCER thought the authors of the papers on enucleation of myoma had performed a useful service in calling attention to the value of the operation, which he supposed every gynaecologist practised and proffered, in suitable cases, to hysterectomy. He was surprised, however, to find no reference in either paper to the most valuable form of enucleation—namely, through the cervical canal. The papers well illustrated the pitfalls of statistics, Dr. Giles (after careful inquiry in a proportion of his cases) giving the percentage of recurrence as 10, Mr. Bonney (without any adequate inquiry) giving it as 0. No doubt the percentage was somewhat greater than that found by Dr. Giles, and it constituted a serious objection to the operation, especially when carried out by the abdominal route and with the added risk of ventrofixation. Mr. Bonney's method of enucleation was ingenious but complicated, and in Dr. Spencer's opinion unnecessary. One danger, the possible infected condition of the tumour, had not been alluded to. He had seen in a virgin a case of fibroids containing abscesses infected with streptococci successfully treated by total hysterectomy. The case, had enucleation been performed, would almost certainly have terminated fatally, as happened in a case in which a conservative Caesarean section was done for an obstructing fibroid infected with the bacillus of gas gangrene. Although infection of fibroids which did not give rise to symptoms was rare, he thought it was important, particularly in cases complicating pregnancy, that a bacteriological examination of the tumour should be made before or at the time of the myomectomy.

THE first meeting of the Royal Medico-Chirurgical Society of Glasgow for the session 1922-23 was held on October 6th. The President, Dr. A. Maitland Ramsay, delivered his inaugural address on "The clinical significance of falling sight." The address covered a wide field, and was illustrated by clinical references. Dr. Ramsay pleaded for a closer co-operation between the ophthalmic surgeon and the family doctor, and showed that "falling sight" was a symptom observed in many disease conditions occurring in family practice.

A MEETING of the Cambridge University Medical Society was held at Cambridge on October 18th, when, before an audience of nearly 500, Dr. G. DRUMMOND ROBINSON, obstetric surgeon to the Westminster Hospital, delivered a lecture on "Normal labour," illustrated by a cinematograph film and lantern slides. The film shown was in two parts, one of a vertex case, the other of a breech case, each subdivided into a diagrammatic part showing the processes of labour as if seen in section, and a part showing the process in an actual case.

Rebiefus.

THE CURE OF LEPROSY.

IN his *Handbook on Leprosy*¹ Dr. ERNEST MUIR, one of those who have had the privilege of applying to Sir Leonard Rogers' researches the acid test of practice, gives clear account of the method of administration of the new and potent remedies provided for the practitioner's use. They are chiefly the fatty acids and ethyl esters derived from hydrocarpus and chaulmoogra oils. Chaulmoogra oil has of course long been known as a popular remedy for leprosy, but when taken internally its benefits were found to be very limited because it always sooner or later seriously upset the stomach. Sir Leonard Rogers, setting himself the task of isolating the active principle of the crude oil, has provided us with the fatty acids and their ethyl esters, which, injected intramuscularly or even intravenously, are free from the objections to which the parent oil is open and form a most potent remedy against the disease. Even in advanced cases excellent results can usually be obtained. It is not too much to say that we are now upon the threshold of one of the greatest triumphs of modern medicine—the control of leprosy. Dysentery, cholera, leprosy, the three dragons of the tropics, have now been robbed of half their terrors by the genius of a single man of science. How shall the legendary achievement of our patron St. George compare with a record such as this? In his modest little volume Dr. Muir tells the story of the commencing subjugation of leprosy in clear and simple terms, such as they who run may read. All those who are in any way concerned with the leprosy problem, whether on the clinical or the administrative side, should buy it, for they will learn much from it. All those who are interested in the achievements of modern medicine should read it, for it marks one of the moments when it is possible to be proud of human effort.

This little book has made its appearance at an opportune moment. The curse of leprosy is as old as history, but it is only during the last very few years that the victims of this terrible scourge have had any prospect before them other than incarceration in a leper asylum to eke out an existence embittered by increasing physical disabilities. To these children of calamity Sir Leonard Rogers has brought new hope. From all over the leper-stricken areas of the world comes report after report of "their asylums or colonies un-
nazed, hardly believing the evidence of statistics of "lesions disappeared," "apparently cured," for the achievement seems too good to be true. On the other hand, lepers in the early stages of the disease, contrary to their wilful habit of concealing their trouble in order to avoid as long as possible confinement to the leper colony, are coming forward in increasing numbers to seek the new salvation.

TUBERCULOSIS.

THE second edition of Dr. POTTENGER's large work on *Clinical Tuberculosis*² is almost a reproduction of the first, which was published in 1917. It consists of two volumes, of which the second contains three more illustrations than appeared in the first edition and twelve more pages, owing to the inclusion of a chapter on influenza and tuberculosis. The first volume deals with the pathological anatomy, pathological physiology, diagnosis, and prognosis of tuberculosis. The author holds that the disease is primarily one of the lymphatic system, the organs being slightly and the regional glands markedly infected; in secondary lesions the reverse is the case. Great stress is laid on the importance of universal testing of children with tuberculin, but it is admitted that a positive reaction should not cause undue anxiety if the child remain healthy. Treatment by tuberculin is strongly advised for children suffering from partially quiescent lesions. All will not concur in these views, and by a good many authorities d'Espine's sign is not considered so valuable an aid in diagnosis as the author believes it to be. Palpation of the tissues on each side of the dorsal spine for evidence of resistance is highly praised for the detection of enlarged mediastinal

glands. The classification of the early symptoms due to toxæmia, reflex causes, and to the tuberculous process *per se* is a valuable contribution to the subject; active tuberculosis, it is maintained, may exist without toxæmic symptoms. The chapters on the nervous system in tuberculosis and on traumatic tuberculosis will well repay perusal. Perhaps too much stress is laid on the presence of hæmoptysis as diagnostic of tuberculosis, and bronchiectasis, in which it is common, finds no mention. The value of tuberculin in diagnosis and prognosis is emphasized, frank and prompt reactions being looked on as positive evidence of active tuberculosis. Objection is wisely made to the advice often given to patients who have lately suffered from tuberculosis to take up some country occupation to which they are not accustomed and for which they are perhaps totally unfitted. A long chapter by Dr. Joseph Pottenger on laboratory methods is included in the first volume. The second volume deals with the complications and treatment of the disease. The authors have found tuberculin of great service in tuberculous laryngitis. Special importance is attached to pleurisy, whether dry or moist, as a cause of tuberculosis; pneumothorax was not found so fatal as is usually supposed. Immediate removal of a tuberculous kidney is not recommended: it is stated that conservative measures should first be tried, and that tuberculin has its uses. A favourable climate, though beneficial, is not essential for the treatment of tuberculosis. Food, rest, and exercise, open air, hydrotherapy, heliotherapy, home treatment, sanatorium treatment, and the numerous factors in the proper conduct of the disease receive thorough consideration, the sanatorium being considered the ideal place for treatment. A warning is given against the all too prevalent custom of removing the teusils from children on the slightest pretext, heedless of their action as protective agents. A history of many cases with an instructive discussion on each of them and a chapter on influenza and tuberculosis complete the volume. As the various chapters may be almost looked upon as monographs in themselves they can be read individually without reference to the rest of the work: this plan necessitates some repetitions, but owing to the excellence of the contents is excusable. The two volumes contain the results of Dr. Pottenger's labours for many years, chiefly as director of the sanatorium of Monrovia, California. The publishers are to be congratulated on the way in which they have carried out their part of the undertaking.

Dr. DAVID C. MUTHU's book on *Pulmonary Tuberculosis: Its Etiology and Treatment*³ is founded, as the author tells us on the title-page, on twenty-two years' observation and work in open-air sanatoriums. The book is divided into three parts, dealing respectively with etiology, treatment, and the social and economic factors of tuberculosis. The author is no believer in the germ theory. Such sentences as the following arrest attention: "The presence of tubercle bacillus is not a decisive factor in the development of tuberculous processes" (p. 13). "Tuberculosis . . . is a deficiency disease" (p. 13). "It is a blood dyscrasia" (p. 13). "Glands may be normal and healthy, and yet may contain tubercle bacilli" (p. 32). We do not think most authorities will subscribe to this statement: "A tuberculous gland may not contain any bacilli whatever" (p. 66). "Cases of phthisis can occur without the presence of tubercle bacilli" (p. 69). "The social, economic, and industrial factors more largely influence the incidence and mortality of tuberculosis than any tuberculous infection" (p. 83). "If we do not know how tubercle bacilli get into the body, it is perhaps because in the majority of cases they do not enter from the outside at all, but are formed within the body" (p. 168). "When tubercle bacilli appear on the scene, they do so as the effect of a cause, as the product of vicious environment; or if they have entered as a saprophyte . . . their pathogenicity is the result of deranged nutrition" (p. 172). It would seem, therefore, that the author does not consider the tubercle bacillus is the cause of tuberculosis; neither does he believe in contact infection, or that the prevalence of tuberculosis in children may be due to cow's milk. The first part of the book concludes with a chapter of twenty-seven pages on the early diagnosis, symptoms, and prognosis, which might have been omitted. Naturally, the author's views on the etiology of the disease prevent him from having any belief in the efficacy of tuberculin and vaccines, which he has found wanting. Sanatorium

¹ *Handbook on Leprosy*. By Ernest Muir, M.D., F.R.C.S., Ed. Cutlack: R. J. Grundy. 1921. (Demy 8vo, pp. 118; 52 figures, 4 plates, 2 plates, Rs. 7.)

² *Clinical Tuberculosis*. By F. M. Pottenger, A.M., M.D., LL.D. With a chapter on Laboratory Methods by J. D. Pottenger, A.B., M.D. In two volumes. Second edition. London: H. Kimpton. 1922. (Med. 8vo, Vol. I: pp. 707, 165 figures, 6 plates; Vol. II: pp. 725, 65 figures, 4 plates. £3 15s. net the two volumes.)

³ *Pulmonary Tuberculosis: Its Etiology and Treatment*. By D. C. Muthu, M.D., M.R.C.S., L.R.C.P. London: Baillière, Tindall, and Cox. 1922. (Demy 8vo, pp. 331; 23 figures. 12s. 6d. net.)

treatment is thoroughly considered in the second part. As a result of his experience the author finds that 80 per cent. in the first stage, 40 to 45 per cent. in the second, and 8 per cent. in the third get well. Such a recommendation as two or three days' excursion in the charge of a doctor at the sanatorium may be suitable for a private institution, but is hardly practicable in a public one. Continuous inhalation is highly praised, but its physiological, chemical, and psychic effects are considered far to outweigh any benefit obtained from its germicidal action. The mask designed by the author is illustrated and prescriptions for the three inhalants he employs are given. The third part contains a chapter on the prevention of tuberculosis; the most important factors in prevention as well as in treatment are considered to be social and economic, and with this opinion most will be able to agree. The volume concludes with a consideration of tuberculosis in relation to marriage and parenthood. The book is interesting, and, though containing repetitions, gives much food for thought.

A GERMAN TEXTBOOK OF PSYCHIATRY.

Dr. PH. JOLLY has written a short guide to psychiatry, intended for the use of students and practitioners. The aim is essentially practical, and theoretical discussions have as far as possible been avoided. The first edition was published in 1913, and the present volume contains some additional matter, notably a description of the Binet-Simon intelligence scale and a brief account of the psychoses associated with or caused by service, military or otherwise. The first part is devoted to general psychiatry, and in successive sections an account is given of symptomatology, diagnosis, pathological anatomy, prognosis, and treatment. In the second part Dr. Jolly gives an outline of the various forms of mental disorder. He approaches his subject in a conventional manner, and confines himself strictly to the descriptive method. Indeed, it is interesting to observe how little German psychiatry, as exemplified in this volume, appears to have been influenced by the interpretative and individual method of Bleuler, Freud, and Jung, while in other countries, and more especially in America, its effects are so apparent. Though the book contains the main facts which the student must know, it is as a whole singularly uninspiring, and no effort is made to interest the reader by means of diagrams or illustrations, or by reference to actual cases. It is of course difficult to include case histories in a small manual, but there is no necessity to make psychiatry quite so uninteresting as the author here succeeds in doing. As the book is only designed to contain the usual subject-matter of the small textbook, it does not include any new work of special interest to the English psychiatrist.

THE SCIENCE OF CHEMISTRY.

IN MELLOR'S *Inorganic and Theoretical Chemistry*⁵ is undertaken the exposition of the whole of the science which relates to the composition of matter and the transformations of its constitution and structure. The whole work is to be completed in six or seven volumes of about 1000 pages each, and of these two have appeared; the first is introductory to the system under which the study is pursued, and in it is considered the chemistry proper of hydrogen and oxygen only; the second volume deals with the halogens and the alkali metals. The other elements are to follow mainly in the order of the periodic table; newer work on the constitution of the atom is to appear in the third volume.

The method and purpose displayed in the elaboration of this treatise are an attraction and give it distinction. We find narrated in it the history of the acquisition of knowledge in the science; the epoch-making discoveries are properly emphasized, and the way in which ideas were evolved and conceptions of theory developed is shown with amplitude of detail. Colour is given to these descriptions by the apposite quotations prefixed to almost every paragraph in the first volume. Of these, two may be cited; the first near the beginning (p. 5), from Aristotle: "The mind is like a blank tablet upon which experience writes that which is perceived by the senses." The second towards the end (p. 569), from

Humphry Davy: "I thank God that I was not made a dexterous manipulator, for the most important of my discoveries have been suggested to me by failures." But it is not to be supposed that the work is intended only for those who take their science in an easy chair; quite the contrary, for every section of the subject is treated with scholarly completeness, and wherever mathematical relationships are important—as in chemistry they grow to be ever more and more—they are fully elaborated.

The highest merit of such a work is that the subject-matter of each section is so set out that each is not only lucid in itself but made to shed light on kindred questions. To achieve this are needed, first, the gift of being a true chemist; secondly, a power of clear expression, for there is no wealth of technical nomenclature in chemistry to compensate the tendency of the English language to slip into ambiguity; and thirdly, the faculty of opportune repetition in altered phraseology which saves the student both fatigue and misapprehension. In these respects the work is particularly excellent; the older foundations of the science are so described as to give them their highest educational value and the newer developments are made to fit into the context of description so as to afford a coherent account of the subject. The author is to be congratulated on having performed a difficult task with great credit. Connexion and coherence of ideas are everywhere apparent, and the view which have attended the genesis and development of

Dates of events are quoted so frequently as the names of experimenters which appear in almost every narrative of experiment. The fault of giving disproportionately large space to the theory and but a meagre account of the facts of experience, which has become common in modern books, is avoided. In this volume we find a wealth of the basic facts of chemistry including many of less ordinary interest which it can be seen are destined sooner or later to acquire supreme interest, and all are given in such connected relation as to build a firm framework.

Volume II, being more occupied with the plainer descriptions of properties of substances and of their reactions, affords less scope for the individuality of the author than Volume I. It will suffice to say of it that the information is comprehensive in respect both of basic facts and their theoretical aspects.

The work contains a sufficient number of figures illustrating apparatus, crystals, including space-lattice systems, curves, and diagrams. References to authoritative memoirs and original papers are systematically given at the end of every section. The indexes are good but might with advantage have been more extensive.

Misprints and errors are rare. In Volume I, at page 104, $\frac{1}{12.8 \times 10^{-20}}$ is inadvertently rounded as 12.8×10^{-20} , but for so

large a volume of matter the number of such instances of oversight are remarkably few. In the same volume (p. 922) is the sentence, "A current of gas is placed [sic] along the annular space between the two tubes"; but one will carp at the choice of the word "placed" for "led" when the work is so well written as to render such a sentence conspicuous.

To the student whose vocation or enthusiasm is to lead him beyond the mere threshold of the science of chemistry this work will prove invaluable, and it is likely to produce disciples who without it might have never been attracted to chemistry. It will be an almost indispensable companion to the teacher of chemistry.

DISEASES OF THE EAR.

THE success which attended the first edition of Dr. Kerrison's *Diseases of the Ear*⁶ has led to the appearance of a second within the space of eight years. The general plan of the first edition, wherein the author sought to describe and discuss fully matters of importance which received scanty attention in the older books, is retained in the new edition, and, in truth, the additions are not of any great moment. There is a short chapter on Bárány's theory of cerebellar control and another on war deafness. The latter seems to be a very short summary of the book *Olites et Surdités de la Guerre* by Bourgeois and Sourdis, which was so helpful to aural surgeons during the war. The alterations in Dr. Kerrison's new edition being slight and chiefly in the form of additional chapters, it follows that, as before, the perspective is good and the book as a whole well proportioned. Especially

⁶ *Diseases of the Ear*. By Philip D. Kerrison, M.D. Second edition, revised and enlarged. Philadelphia and London: J. B. Lippincott Company. (Med. 8vo, pp. xxi + 595; 335 figures, 5 plates. 35s. net.)

⁴ *Kurzer Leitfaden der Psychiatrie für* . . . Von Dr. Ph. Jolly, Privatdozent für Psychiatrie an der Universität Zürich. Second revised edition. 1922. (Demj 8vo, pp. 264. M. 43; bound, M. 55.)
⁵ *A Comprehensive Treatise on Inorganic and Theoretical Chemistry*. Vol. I and Vol. II. By J. W. Mellor, D.Sc. London and New York: Longmans, Green, and Co. 1922. (Roy. 8vo. Vol. I, pp. xv + 1065; 12 figures; Vol. II, pp. vi + 894; 89 figures. 43 3s. net each volume.)

to be commended are the sections on operations and on intra-cranial disease. The details of myringotomy might have been given with more precision, but the mastoid operations and their extensions are well described, though the reader is left a little uncertain as to what the author regards as the most satisfactory after-treatment of the simple mastoid operation. Ossiculectomy is described, but the reader is given to understand that the author has never performed it, and does not recommend it. The chapter on facio-hypoglossal anastomosis, however, is half-hearted and unconvincing. In an American work a certain tolerance as regards language must be granted from the British point of view, and with this reservation it may be said that the writing is good, though at times it is apt to become colloquial. It is, however, fairly free from Americanisms, though such a word as "bleunostatic" gives pause for a moment.

We feel, however, that the present edition might have been brought more thoroughly up to date, especially had the writer given more attention to his British colleagues. For instance, in oto-sclerosis, although the views of Gray are quoted, they are not his most recent views. Again, the author still speaks of the sclerotic mastoid and makes no mention of the researches of Cheate, now classical, although he does mention that in some temporal bones the sclerosis does not appear to be associated with tympanic disease. The work of Fraser on suppuration in the labyrinth and the work of Scott and Jenkins on meningitis also go unmentioned. Perhaps unkindlier still is the illustration of Ballance's flap in the plate devoted to plastic operations on the meatus. The flap is represented as cut upside down. This is worse than mere neglect. It seems, therefore, that the author has confined himself too closely to American and German literature, and that had he expended as much care on the second as he did on the first edition he could have done still better. Though we have felt bound to call attention to certain faults we cannot give higher praise than to say that we know of no better book on the subject.

THE ENCYCLOPAEDIA MEDICA.

In a foreword to the eighth volume of the second edition of the *Encyclopaedia Medica*, the indefatigable editor, Dr. J. W. BALLANTYNE, explains the reasons, such as the war, the high cost of production, and the sudden death early in 1920 of Mr. C. E. Green, the originator of the scheme of this huge undertaking, which have delayed the appearance of this revised edition; he is now able to say that the remaining four volumes should appear at intervals of six months or thereabouts.

The volume before us extends from "labyrinth" to "mammary gland," and in addition to a large number of shorter articles contains thirty-four principal articles dealing with the diseases of the larynx, liver, lungs, lymphatic system, the mammary gland, and malaria. There are new articles on diseases of the lacrimal apparatus by Mr. H. M. Traquair, on lethargic encephalitis by Professor J. M. Beattie, on lumbago by Dr. Alexander Goodall, on lunacy by Sir John Macpherson, on tuberculosis of the larynx by Dr. A. F. Hewart (who has also assisted Sir Robert Philip in the revision of the articles on pulmonary tuberculosis and pneumoconiosis), and on the surgery of the lungs and thorax by Mr. Frank E. Jardine. Some alteration in the authorship of the articles has naturally been necessitated by the passage of time; thus Dr. Norman Walker has handed over his article on lupus erythematosus for revision to Dr. R. Cranston Low; the article on malaria has been revised by Dr. J. G. Fowler, that on leprosy has been largely rewritten by Lieut.-Colonel D. G. Marshall, and Professor G. H. Wilson (now of Birmingham) has assumed responsibility for the account of leucocytosis originally contributed by his teacher, Professor R. Muir. In the much-enlarged article on tropical, parasitic, and other diseases of the liver Sir James Cantlie has had the able assistance of Dr. Aldo Castellani, and Mr. D. M. Greig has helped Sir Harold Stiles in the freely illustrated account of diseases of the mammary gland. The description of lethargic encephalitis has been condensed into rather less than four pages, and the protean character of the clinical manifestations has hardly received sufficient notice. In the revision of his important article on leuco-erythæmia Professor G. Lovell Gulland speaks of the more rapid and certain action of radium as compared with that of

x rays, and ascribes it to the superior penetrating effect of radium and not to any essential difference in action, so that the greater penetrating power now obtainable with x rays will probably be equally effective. In the treatment of lymphadenoma he has recently tried injections of colloidal copper with good effect, which may be due to the well-marked febrile reaction, which is possibly of the nature of protein shock.

This instalment fully maintains the reputation that the *Encyclopaedia Medica* has won, and the editor may be heartily congratulated on the continued success of his efforts.

NOTES ON BOOKS.

IN a handy volume, *Vaccins et sérums*⁸ (the first of the *Bibliothèque des connaissances médicales*, which he is also editing), Dr. APERT, physician to L'Hôpital des enfants malades, Paris, gives a clear summary of our present knowledge of the subject, together with some account of the changes that take place in the body after injection of vaccines and serums. This is prefaced by an account giving the history of Jennerian vaccination, of Pasteur's work, and of antidipteric serum. Other antitoxic serums, those for tetanus, botulism, and cobra venom, are then described, and separate chapters are devoted to the serum and vaccine treatment of the various infections. The account of the treatment of bacillary dysentery contains a long extract from an article published last year by d'Hérelle on bacteriophages. The work of Floxner on antimeningococcal serum is mentioned, but the well-known researches of the Rockefeller Institute on the strains of the pneumococcus and the serum for cases of pneumococcus type I infection are not referred to, though a multivalent serum prepared against types I, II, and III by Truche of the Pasteur Institute is noticed. In reference to Coley's fluid Roger's view that the active agent is *Bacillus prodigiosus* and not the streptococcus finds a place. The serum treatment of gangrene and haemophilæ occupies a chapter, and there is a good description of serum disease. Lastly, the anti-anaphylactic method of treatment is summarized, with an account of Danysz's administration of vaccines, obtained from faecal bacteria, for various chronic diseases, such as eczema, dyspepsia, and intestinal disorders.

There certainly have been—and perhaps there are now—medical poets of the first water. But, with the exception of Professor Henry Towns, we cannot call to mind any medical painter whose work can be thought of as comparable in its own way with the exquisite poetry of Keats or the polished verse of Goldsmith and Bridges. Pictorial art, unlike poetry, seems seldom to have drawn any man away from medicine. We are moved to this reflection by fludding among the miscellaneous volumes sent to us for review a copy of Mr. HENDERSON's pleasant book on *Romney*.⁹ Many of our readers will probably enjoy it, but it has little or nothing to do with doctors or doctoring. George Romney painted one or two medical portraits (for instance, that of Joseph Allen, M.D., in the Dulwich College collection, painted in 1778), and one of his early pictures showed the arrival of Dr. Slop on a memorable occasion in the history of Tristram Shandy. He had painted Sterne's portrait at York, and as Mr. Henderson says: "Probably Romney knew by sight Dr. Barton (a deformed person with a very large head) who was said locally to have been the original of Dr. Slop. The people of York were accustomed to the appearance of this acconcheur riding mud-spattered astride his stuy pony." Beyond these slender threads we can trace no direct relation between our profession and this delightful English artist whose work is perhaps in greater esteem to-day than at any previous time. It would be out of place, therefore, with so many medical works clamouring for attention, to dwell further upon a small volume whose claim is upon the physician's *horæ subsecivæ*.

In his volume, *A History of the Association Psychology*,¹⁰ Professor HOWARD C. WARREN gives a comprehensive account of the associationist movement and endeavours to trace back recent developments of psychology to their source in the writings of this school. The book is the product of careful historical research and constitutes a valuable addition to the literature of psychology. An exhaustive bibliography is appended, giving references to the ancient and mediæval writers, to the British and Continental contributors to the associationist doctrine, and to the more recent investigations of association problems.

Nova et Vetera.

THEOPHRASTUS RENAUDOT, M.D.,

ORIGINATOR OF NEWSPAPERS.

OF few human institutions can it be said that they had their beginning at any definite date. When we get back to the man who seems to have a good claim to be considered the founder we find that he was preceded by others who had the same idea but not the wit or opportunity to work it out. Subject to this qualification, it may fairly be said of Théophrastus Renaudot, Doctor of Medicine of the ancient University of Montpellier, that he was the founder of the newspaper, if by that term we understand a paper published at regular intervals and giving the news of the day. Broad-sheets had been issued during the later part of the sixteenth century in Italy and Spain, and also in the Netherlands, but they appeared only when material had accumulated to fill them, and interruptions of communications, owing to stormy seas and miry roads, were frequent. In fact, regular publication could not be attempted until the postal service had reached a stage of development which made it possible to receive the news and distribute the paper at fixed dates.

Some have seen an anticipation of Renaudot's newspaper enterprise in the *Mercurius Francicus*, started in 1605, itself modelled on the *Mercurius Gallo-Belgicus*, first published in Cologne in 1594; but these were both of the nature of annuals—forerunners of the *Annual Register* founded by Edmund Burke in 1759 and still continued.

Of the facts of Renaudot's life very few are beyond dispute; during his life he indulged in endless quarrels and controversies, and his many and very bitter enemies found any stick good enough to beat such a cur as they held him to be. He was born at Loudun in Poitou in 1584, though some say 1586; he died in Paris on October 25th, 1653, and was buried at St. Germain l'Auxerrois before the parish altar, the coffin being followed by thirty priests and a large concourse of people. So much is admitted, and it is not disputed that he opened an office in Paris, where inquirers could obtain the address of any citizen and persons in search of employment could register their names; nor that he obtained permission to publish a gazette; nor that he set up a *maison de prêt* or pawnshop. The many "innocent inventions" of his later life make it easy to believe that he was a clever and precocious boy, who left his native town to study surgery in Paris at a very early age. He did not go through the regular mill there, but in 1606, when 22 (or 20) years of age, went to Montpellier, where the Faculty gave him the degree of M.D. after three months' residence. This was the root of many of the troubles of his later life. What befell Renaudot during the next six years is disputed. According to his own account, he spent several years in travel, studying medicine at various centres, then settled as a physician at Loudun and quickly gained a great reputation throughout Poitou and the neighbouring provinces. His enemies alleged that from Montpellier he went straight back to Loudun, and failing in practice had to become a teacher in a school to keep body and soul together.

However this may be, there seems no doubt that he went to Paris in 1612 to practise as a physician, but again, according to his enemies, had to become a school teacher, eking out a living by taking boarders. He, however, asserted that he was at once appointed a physician to the King with a salary of 800 livres a year. His enemies did not dispute the appointment, but alleged that it was a mere title, easily obtained, and not carrying any salary. Even so, it must have served to regularize his position to some extent, and it is remarkable that a young provincial—he was at most only 28—should have received the title, if it were no more. The explanation given is that he was befriended by Richelieu, then the all-powerful minister, ever ready to attach to himself men of talent and energy, more particularly if they came from his own province of Poitou. This theory seems the more probable in view of the concessions or privileges he received subsequently. He encountered much opposition and appears after a short time to have gone back to Loudun. But he returned to Paris, and in 1630 finally got leave to open his registry office (*Bureau d'Adresse*) and to start his *Gazette*, the first number of which appeared on May 30th, 1631. In planning and conducting it he is said to have been greatly helped by a famous genealogist, P. Hozier, whose occupation led to his having a very large number of correspondents in France and other countries; Richelieu communicated official documents,

and it is even asserted that Louis XIII was an occasional contributor. Two numbers were published weekly, the one entitled *Gazette*, the other *Nouvelles Ordinaires*. In addition, supplements were issued from time to time containing individual narratives and official documents. At the end of the year the various documents were gathered into a volume, and issued with a preface under the general title *Recueil des Gazettes*. A writer in the *Literary Supplement* last year stated that Renaudot had three correspondents in England—one in London, another at Chester for Ireland, and a third at Berwick for Scotland. They wrote weekly letters, and special attention was given to British affairs both in the *Gazette* and the annual *Recueils*. Advertisements were not inserted in the *Gazette*, but were printed in a separate sheet, *Feuilles du Bureau d'Adresse*; this no doubt meant a considerable economy in printer's charges.

In his plan for a registry Renaudot was anticipated in England, where Sir Arthur Gorges and Sir Walter Cope obtained letters patent for a Public Register for General Commerce in 1611, but as they had neglected to obtain the right to charge fees the scheme was abandoned. It was not until some forty years later that it was revived, and an office of General Accommodation by *Adresse* was opened in Mr. Fisher's house in King Street, Covent Garden. Henry Robinson, a city merchant and writer on economics, also set up an Office of Addresses and Encounters in Threadneedle Street. In his newspaper enterprises Renaudot had several imitators in England; the *London Gazette*—at first called the *Oxford Gazette*, for the Government had removed there to avoid the plague—appeared first in 1665. At about the same time his advertisement sheet was imitated in London by the issue of a weekly sheet of advertisements called the *City Mercurie*.

It may also be claimed for Renaudot that he was a pioneer of the meetings for scientific discussion which have now come to play so important a part in the progress of knowledge. He invited persons of a scientific or curious turn of mind to assemble at his registry office to discuss subjects announced beforehand in his advertisement sheet, and published reports of what took place. Richelieu founded the French Academy in 1635, and it is possible did not regard this "invention" as innocent.

In spite of all the other ironies he had in the fire, Renaudot continued to practise medicine himself, and imported doctors from the University of Montpellier and other provincial universities to assist him and to help in the distribution of certain secret remedies, apparently all of them containing antimony. He established a kind of free clinic for the poor, and announced that the King had given him a site on which he proposed to erect a building for this purpose. According to law only graduates of the University of Paris could practise in that city. In 1566 the prescription of antimony as a drug had been condemned by the highest legal authority in Paris, the Parlement, and the majority of physicians in Paris, led by Guy Patin, still strongly objected to its use. Eventually the Faculty raised an action against Renaudot on various grounds. It has generally been assumed that the opposition of the Faculty to Renaudot and his associates was due to pure prejudice, but it must be admitted that the Faculty had good grounds to object to some of Renaudot's proceedings, and in particular to his combination of medicine and pawnbroking; even as a pawnbroker his hands were not clean. The court by which the case was first heard found against Renaudot and his provincial friends on December 9th, 1643, and forbade them to practise or to hold the meetings. Renaudot appealed to the higher court (the Parlement), which not only rejected his appeal (on March 1st, 1644) but suppressed his pawnshop, on the ground that it was injurious to the public interest, and directed all the objects pledged to be returned to the owners; he was allowed to continue his registry office and *Gazette*. In spite of the judgement against him Renaudot continued to practise and to sell his remedies, and lived long enough to see the condemnation of the use of antimony withdrawn. Towards the end of his life he was made historiographer to the King and died at the Louvre in, as has been said, 1653. In one way and another Renaudot must have made a good deal of money, but seems to have kept little of it. Guy Patin alleged that he died in poverty, but others assert that he left a modest fortune.

Of Renaudot's three sons two took to medicine; both had difficulties with the Faculty and had to go to law to obtain admission. Both, however, were admitted during their father's lifetime, though they had to disavow his conduct and

to promise to have nothing to do with the registry office; no formal objection, however, was made to the continuing the *Gazette*, which went on until 1692. The younger of the two, Eusebius, became physician to the Dauphin and Dauphine, and had among his fourteen children a son, also Eusebius, a distinguished theologian and Orientalist, and a member of the French Academy.

THE HEALTH OF THE SCHOOL CHILD.

The annual report of the chief medical officer of the Board of Education¹ for 1921 has taken a new form, for this year it is compressed into a hundred pages "on the ground of economy," and the familiar blue cover is missing. The most noteworthy part of the report is a general survey of school medical work and of its meaning.

School medical inspection was established by Act of Parliament in 1907 for two principal reasons: First, it was found that many school children failed to reap advantage of a compulsory system of free national education on account of physical disability, and that the only way to detect its extent and secure prevention or remedy was a system of universal medical inspection. Secondly, as time passed it became evident that a close and vital relation existed between the physical condition of the child and the health and capacity of the whole population. Thus the State was compelled for the sake of the national well-being to deal with the physical condition of the school child. John Colet in the sixteenth century and John Locke in the seventeenth insisted that the physical fitness of the child lay at the foundation of its education, and this was demonstrated in the nineteenth century by Ware, Priestley Smith, Dukes, Warner, and others in this country, and by many workers abroad. At present there is in being a national system of medical inspection and supervision of the school child. The system is not complete or adequate because the obligation of medical supervision has only existed during the last four difficult years; it is not yet being worked perfectly and therefore is not yielding its fullest results; but it is available and it is universal. Medical treatment is but partial in its scope and prevention, and inadequate in degree; and we are still, in many educational areas, lacking such elementary auxiliaries and equipment as sanitary schools, satisfactory playgrounds and open spaces, manual and craft workrooms, school baths, open-air classrooms, and the apparatus and space for adequate physical training.

Scope of School Medical Service.

The fundamental objects of the school medical service are the inspection and supervision, not only of children known or suspected to be weakly or diseased, but of all children attending school. The child is inspected and, if found defective, is referred for treatment, is "followed up," and is subsequently reinspected. In practice this means an annual medical examination of $2\frac{1}{2}$ million children. The total number of medical practitioners engaged (whole or part-time), including specialists for consultation, is now approximately 2,000; besides, there are some 3,000 school nurses partly or wholly occupied in school work. The adequacy of the treatment, the problem of the irresponsible or indifferent parent, and the manner of the provision of treatment are in turn considered in the report. At the present time two facts are evident: first, that the majority of the parents of children in elementary schools who need medical treatment cannot pay a remunerative fee; second, that the person to provide the treatment should whenever practicable be the general or special medical practitioner. Private practitioners cannot, however, afford to work for nothing or for an unremunerative fee, and are often not in a position to deal adequately and in detail, day by day, with the common defects of school children, such as defective vision, carious teeth, adenoids, ringworm, and minor ailments. The remedy is generally held to be the school clinic, with a restriction that it should treat only the kinds of malady which cannot as a rule be dealt with in private practice.

The very success of the clinic, the report states, may prove its hurt; 291 out of 316 authorities have established clinics. It is urged that the authorities should periodically examine their institutions to learn whether their work deals exclusively with the conditions of disease prescribed, and not with maladies outside the schedule; whether there are

adequate charges to parents who can pay; whether the accommodation is sufficient, and the medical and nursing staffs are competent.

Co-ordination of Public Health with Education Authorities.

The national aspect which this school work assumes has necessitated the linking-up of the work with the general public health service of the country, hence the co-ordination of the work with the Ministry of Health, provided in the Act of 1919—a feature which is real, notwithstanding that it is inevitable that school children must be considered, inspected, and treated as school denizens, and not at large. So that it comes about that of the 316 school medical officers who are the chief medical officers of the education authority in the different areas, 283 are also the medical officers of health of the sanitary authorities in the same areas thus joining in one medical officer the two services, as they are joined at the Board of Education and the Ministry of Health.

From the initiation of this medical work in the schools a substantial and increasing part in medical treatment has been taken by general and special medical practitioners. For obvious reasons these cannot, as a rule, devote the necessary time to the day by day routine duties of inspection in the schools. But the medical treatment which may be necessitated is performed in large measure by them in hospitals, clinics, or other centres, as well as in private practice in the homes of the children. In this way a very large amount of new medical work has fallen to their lot as a result of the school medical service.

Direct medical treatment of the physical and mental defects of school children is not the only, or indeed the appropriate, method of dealing with some of the disabilities of school age. There must be an educational provision. This is found in the system of special schools for the blind, deaf and dumb, feeble-minded, epileptics, tuberculous, cripples, and in the provision of open-air schools for the feeble of health. These provisions are costly but not wholly unremunerative, for it is found that 50 per cent. of the blind, 80 per cent. of the deaf, 75 per cent. of the cripples, and some 40 per cent. of the mentally defective can be equipped for independent wage-earning. This is no small achievement.

The cost of the school medical service as regards inspection and treatment for the year amounts to £1,300,000; the special schools cost an almost equal sum; these, with the provision for physical training, evening play centres, nursery schools, and the provision of meals bring the total to £2,982,000. The average cost of the strictly medical service is about five shillings for each school child in attendance at the elementary schools.

Special note is made of the desirability for the teaching of hygiene in schools. An illuminating statement is made of the manner in which this teaching may be made of the highest value to the child:

"There is no subject in the school curriculum which has a more romantic story behind it than the triumphs of the progress of hygiene in recent years, and the story has the advantage of being always new and expanding. It can be told in the simplest language, and it is woven into the geography and history of the world."

The School Child and Industry.

In the succeeding sections of the report summaries are given of the work done in the educational areas, with special references to the findings of the school medical officers of some of the areas. In the final section of the report reference is made to the necessity for correlation of the duties of the school medical officer and of the certifying factory surgeon. In the Leicester area some of the medical officers do the double duty, to the greater effectiveness of their work. Dr. Joseph of Warrington, after a special investigation into the matter, concludes that one thing is abundantly manifest, that after all the care and expense bestowed both on the child's education and his physical welfare during school life there is an enormous waste of valuable effort and material through the slipshod manner in which a large proportion of our future citizens are allowed to drift into any form of occupation; and it seems to him very probable that if more attention were paid to this matter there would be in later years less industrial unrest among adults.

Unsuitable employment on the one hand, and the ill health and insufficient physique of an adolescent in relation to his employment on the other, are two fruitful causes of unrest and instability of youth in industry. It is a problem for the solution of which medicine must join hands with common sense, and education with social understanding of industry.

British Medical Journal.

SATURDAY, OCTOBER 28TH, 1922.

THE PANEL CONFERENCE.

THE time of the Annual Conference of representatives of Local Medical and Panel Committees, held in London last week, was chiefly occupied in considering the position that is likely to arise when the present contracts between the Ministry of Health and insurance practitioners terminate at the end of next year. The scope of such deliberations is of necessity very wide, and much ground has to be covered before the issues can be narrowed down to practical dimensions. A full report of the Conference is given in the SUPPLEMENT this week. The motions put forward by the Insurance Acts Committee and the amendments thereto served as a basis for discussions which were in effect consultations between the representatives of the Local Medical and Panel Committees and the Insurance Acts Committee on matters of policy likely to be raised in the event of pressure being brought to bear on the medical profession to accept undesirable terms of service in the future.

After agreeing to the system of collective bargaining in dealing with the Government, the alternative policies that might be adopted in case of refusal to serve were critically examined in the light of local information from the various Panel Committee areas. The opinions expressed naturally brought into prominence not only the wide differences of conditions obtaining in various types of practice, but also as great divergencies of conditions in different areas of the same type, such as colliery and industrial districts, and emphasized the complexity of the problem of finding a scheme capable of universal application. The outcome of this debate was an instruction to the Insurance Acts Committee to prepare a revised scheme, which will in due course be circulated to all insurance practitioners, discussed by all Local Medical and Panel Committees, and finally brought before another conference of Local Medical and Panel Committee representatives.

Three other matters of importance seem to call for brief reference here. The question of friendly society control of insurance practitioners did not come before the Conference directly, but it was manifest that opinion on this point was, if possible, stronger than ever. At the same time the desire of the profession to meet these bodies and any other persons interested, with a view to improving the medical service, was clearly demonstrated by the adoption of a motion authorizing the Insurance Acts Committee to promote such a conference. In the second place the Conference generally showed concern for a closer working agreement between the different organized groups of the profession, and more particularly in regard to recent negotiations between the Insurance Acts Committee and the Medical Practitioners' Union. Some disappointment was expressed at failure to report definite progress under this head, but the subject was left on the understanding that consideration of it was proceeding; a definite announcement was promised at as early a date as possible. In order to allow the Insurance Acts Committee a free hand in this matter sanction was given to the increase in the number of representatives on the subcommittee charged with the duty of negotiation. Thirdly, the report to date of the National Insurance Defence Trust Fund was more encouraging than at previous conferences, but it would be idle to pretend that it is what it should be. If

the fund is to be an index of the quickening of the mind of the profession to its possible needs in the future, the next six months ought to show a very different rate of augmentation.

On the whole the Conference accomplished a satisfactory amount of preliminary spadework in digging the necessary foundations of an organized plan of campaign against possible future contingencies. There was a noticeable reluctance on the part of some members of the Conference to underestimate the difficulties in their constituencies. However disappointing this may seem at the moment, it is a healthy sign. If the Conference is to fulfil its purpose it must reflect accurately the opinions of the main body of insurance practitioners. The picture must not flatter, but be a plain, "speaking" likeness. Some whose personal enthusiasm and ideals lead them in the excitement of debate to give too rosy a view of their local organization no more help the Conference than those who, having only, as it seems to them, unsatisfactory conditions to report, are tempted to keep silent. Representatives of Local Medical and Panel Committees have now to educate their constituents to face the grave difficulties in front of them; they must measure and develop the spirit of sacrifice, without which no real success is possible; the main body of their constituents must learn that the best central organization can be paralysed by apathy and inactivity at the periphery.

THE ANNUAL REPORT OF THE BOARD OF CONTROL.

No longer can the problem of mental disorder in general and the welfare of the certified insane in particular be regarded as the exclusive concern of those who are actually engaged in the care of the mentally unsound and the management of asylums; the problem is one of great social importance, and it thus becomes the concern of the community as a whole. This fact is now being more generally recognized, and for this reason the Report of the Board of Control, which is responsible for the supervision of 123,714 notified insane and 13,810 mentally defective patients, tends to receive more attention from the general public at the present time than was formerly the case. It is well that it should be so, because the Report contains a number of interesting facts and comments, and it shows the magnitude of the work for which the Board is responsible and the difficulties with which it is confronted in endeavouring to carry it out satisfactorily.

The prefatory note describes the year 1921 as having been one of great administrative difficulty. The unfavourable financial conditions prevailing throughout the country rendered it necessary to adopt a policy of the strictest economy, with the result that many matters important for the treatment of asylum patients and the conditions under which they live had to be postponed. It is, perhaps, not the asylums, however, which have suffered the most from the existing financial conditions. Rather is it the development of work under the Mental Deficiency Act which has been most retarded owing to the need for economy. Fortunately, as the Report shows, the Geddes Committee recognized the work of the Board of Control in relation to mental deficiency as essential to the physical and moral health of the nation, and refrained from suggesting any reduction in the vote. Certain concessions have been made for 1922-23 which it is hoped will enable local authorities to deal with new "urgent" cases which may arise, but the whole position in regard to mental defectives is most unsatisfactory, and the problem they create cannot be effectively dealt with under present financial conditions. In areas where ascertainment has been

thoroughly carried out it is found that the number of cases requiring institutional care is far in excess of the number for whom an Exchequer grant is made. Where branch associations of the Central Association for Mental Welfare have been established valuable work is being done in spite of adverse financial conditions, and we are glad to observe that the Report includes a well-deserved tribute to the work of this organization. By providing for the supervision of cases for whom institutional care is not available or not desirable, by organizing occupation centres, and supplementing the activities of the statutory committees, the Association has carried out work of incalculable value to the community.

On January 1st, 1922, the number of notified insane in England and Wales showed an increase of 3,370 on that recorded on January 1st, 1921. The main factor in the increase during 1921 was the very low number of deaths in asylums. The death rate calculated on the daily average number resident was 8.37 per cent., or 0.27 lower than in the preceding year, which was the lowest previously recorded. The causes of death are divided into primary and secondary or contributory. The number of deaths from tuberculosis amounted to 1,497. The rate per 1,000 reckoned on the total incidence was 15.6, as compared with 13.6 for primary cases only, the number being increased by the addition of "secondary" cases from 1,304 to 1,497. Dysentery, from which 183 deaths were returned as the "primary" cause, was actually present in 237 cases, these therefore representing the total incidence of death from these causes. A careful analysis of the returns furnished of the occurrence of dysentery and diarrhoea in the county and borough asylums is included in the Report, and an interesting record of researches now in progress at a number of asylums indicates that every attempt is being made to lessen the incidence of dysentery in these institutions.

The resumption of full medical records, which had largely been suspended during the war, has now allowed of a return to the pre-war practice; and the tables dealing with the "Causes of Insanity" for the year 1920 have been duly prepared and filed at the office of the Board for reference. A summary of causes and associated factors in insanity stated that insano heredity was found in 15.4 per cent. of males and 22.4 per cent. of females, both less than that discovered in the years 1909-13. A psychopathic family history is, however, probably present in a much greater proportion of insane cases than these figures indicate. The sources of error are manifold. In some cases no history is ascertainable, and in others it is concealed by the relatives; moreover, some medical officers take more trouble to obtain an accurate history than do others. In spite of the fact that, as far as these tables are concerned, prolonged mental stress appears to be the most frequent causal factor in the production of insanity, we fear that the hereditary factor has a far greater influence than the figures indicate. It is of sociological interest to observe the decline in the share taken by alcoholism and inebriety in the etiology of insanity, which in 1920 yielded a rate amongst females only one-half that in 1909-13, and in males not much above one-half. The value of some of the statistics is diminished on account of the method of classification adopted in asylums. The Board recognizes that a more modern nomenclature of the forms of insanity is necessary, and it is much to be desired that one more in harmony with present-day psychiatry will before long be adopted.

Adverse comments are made in the Report on the tendency of some Poor Law institutions to retain cases of acute insanity for whose care and attention mental hospitals have been especially provided. It is pointed out that the wards of a Poor Law institution are not well adapted for acute mental cases, and that it was never intended that such cases should remain in them

for more than a short period of observation. The Board considers that even if the law remains unchanged the principle which obtains in certain districts of sending all cases of mental disorder to the mental hospital through the Poor Law institution is to be deprecated, and goes on to observe that, although it is possible in some cases to avoid the so-called stigma of certification, direct admission to the mental hospital is the wisest course. Many of the patients now detained in Poor Law institutions, where expert treatment is impossible, are essentially those for whom it is necessary to amend the existing lunacy laws, so that they may be able to obtain the most appropriate and up-to-date treatment for a period without certification.

The Report includes some important recommendations in regard to the question of voluntary boarders in registered hospitals and licensed houses. As a result of certain complaints which have been made it is suggested that a printed notice setting out the main facts should be handed to the boarder on his arrival, in order that he should be under no misconception as to his position, and should be fully aware of his right to leave on giving notice. Another important recommendation is made in regard to the certification of the voluntary boarder—namely, that he should never be placed under certificates while in residence, unless such a course be absolutely necessary for the safety of the patient or for the protection of the public. We are in entire agreement with these suggestions, and feel that if, as is most desirable, the voluntary system should be extended to the borough and county mental hospitals similar procedures should be carried out. It is only by adopting an attitude of complete frankness towards the patient who voluntarily places himself under treatment that the mental hospitals of the future will succeed in gaining the complete confidence of the public.

THE "VICTORY": 1805-1922.

ADMIRAL OF THE FLEET SIR F. C. DOVETON STURDEE is making an appeal on behalf of the Society for Nautical Research for funds to save the *Victory*, and to restore her, so far as money will permit, to her condition at Trafalgar. The Admiralty has moved the *Victory* into a dock consecrated to her sole use and has supported her sound timbers by an iron cradle, but has no funds to do more. But more is necessary if she is to be maintained as a reminder of the great days of the British Navy. She was laid down in 1759, and before Trafalgar had seen much service, for she was the flagship of Sir John Jervis when, with 15 ships against 27, he won the great victory of St. Vincent. She was the flagship of Lord Hood when he occupied Toulon and conquered Corsica; of Lord Howe when he relieved Gibraltar after three years of siege, and also of Keppel and Kempenfelt. Her surgeon at Trafalgar was Beatty, afterwards Sir William Beatty, who had joined on December 14th, 1804. He had as assistant surgeons Smith and Westenberg, and after the battle was joined by Surgeon Britton, of H.M.S. *Pickle*. Beatty's carefully compiled journal states that on the *Victory* prior to the battle there were five deaths and two hospital cases. Of the deaths one was from fever, three from consumption, and one from injury to the spine. The two patients in hospital were both suffering from consumption. At the battle there were 102 casualties, with five deaths, besides that of Lord Nelson. Five of the worst cases were left at Gibraltar, and five had not recovered from their wounds when the vessel was put out of commission at Chatham. All the others recovered on board. The five deaths were Midshipman Alexander Palmer, shot through the thigh, who died of tetanus on October 28th; Henry Cranswell, seaman, who sustained multiple contused wounds and simple fracture of the tibia and fibula, and died on October 25th from gangrene; Joseph Gordon, seaman, who underwent amputation of the thigh, and died after a sudden spasm on October 27th; William Brown, seaman, wounded by grapeshot through the lower part of the left

thorax, who died on October 23rd of internal hæmorrhage; and Richard Jewell, seaman, who underwent amputation of the thigh through the great trochanter on October 23rd and died shortly after. Beatty, in his *Authentic Narrative of the Death of Lord Nelson*, relates how on the morning of October 21st Lord Nelson fastened on his coat besides the Orders of St. Ferdinand, the Crescent, and St. Joachim, the Star of the Order of the Bath over his heart. The *Victory* had been laid alongside the *Redoubtable*, so that it was almost possible to leap from one to the other, and upon the mizzen-top of the *Redoubtable* were posted two seamen with muskets. Lord Nelson was standing on the quarter-deck talking to his captain, Sir Charles Hardy—his secretary, Mr. Scot, had already been shot beside him, and some of his blood soiled Lord Nelson's coat. The distance from the mizzen-top of the *Redoubtable* was not more than fifteen yards: one of the French seamen fired and hit Lord Nelson. The ball entered just below the left epaulette, fracturing the acromion, and, descending obliquely into the thorax, fractured the second and third ribs; it passed through the left side of the lung, dividing an artery; it entered the left side of the spine, between the sixth and seventh dorsal vertebrae, fractured the left transverse process of the sixth, and the right transverse process of the seventh vertebrae, wounded the spinal cord, and, passing through the muscles of the back, lodged about two inches below the inferior angle of the right scapula, where it was found with a portion of gold lace, a piece of the epaulette. Lord Nelson recognized that he had been shot through the spine, and that he had lost sensation and movement below the level of the injury. He suffered greatly from thirst and difficulty in breathing, owing to hæmorrhage into the pleura, which he bore with exemplary fortitude until he died, two and three-quarter hours after being wounded. As there were no embalming materials on board, his body was placed in a cask filled with brandy, which was changed twice on the voyage home. On arrival the viscera were removed, when all the organs were found free from disease and deterioration. Owing to inherited gout he had not taken meat or wine for two years. At the same time Beatty examined the injury and removed the ball. Beatty, when he wrote his book (1807), styled himself Physician to the Fleet. In 1817 he became M.D. of St. Andrews, and was admitted to the order of Licentiates as it then existed of the Royal College of Physicians of London. In 1818 he was elected F.R.S. In 1822 he became resident physician to Greenwich Hospital; he was knighted by King William IV in 1831. He retired in 1840; he died unmarried in 1842, and was buried in Kensal Green Cemetery, but the spot cannot be identified. We are indebted for most of the facts here stated to a paper by Dr. S. D. Clippingdale, published in the *Journal of the Royal Naval Medical Service* in 1915.

THE HARVEIAN COMMEMORATION.

IN accordance with custom and in compliance with Harvey's instructions in the indenture by which he founded the Harveian Festival, a dinner was held within the Royal College of Physicians of London on the evening of St. Luke's Day, when the Oration, published last week, was delivered. The guests were the Bishop of Worcester, Assistant Chaplain-General to the Army during the war (1916-19); Sir Aston Webb, K.C.V.O., President of the Royal Academy; Sir Anthony Bowlby, K.C.B., President of the Royal College of Surgeons of England; Sir Robert Hill, K.C.B., Medical Director-General R.N.; Mr. H. J. Waring, F.R.C.S., Vice-Chancellor of the University of London; Sir Stanley Leathes, K.C.B., First Civil Service Commissioner; Mr. T. J. C. Tomlin, K.C., senior standing counsel to the College; Sir John Thomson-Walker, F.R.C.S.; the Master of St. John's College, Cambridge (Dr. R. F. Scott), and the Master of Gonville and Caius College, Cambridge (Sir Hugh Kerr Anderson, M.D.). The President, in proposing the toast of "The Guests," recalled that St. John's was the College of Linacre, the founder of

the College of Physicians, and Caius the college of Harvey. The health of the Harveian Orator was proposed in eloquent terms by the senior consor, Dr. Raymond Crawford, and briefly acknowledged by Dr. Chaplin.

THE MOTOR SHOW.

THE International Passenger Car Show, commonly called the Motor Show, will open on Friday next, after a private view on the previous day. We propose to publish in our issue of next week (November 4th) an article by Mr. Massac Baist describing the show, at which, as he told us last week, this autumn's products alone will, with a few exceptions, be exhibited. This show is the principal event in the motor world, when manufacturers submit their newest types of cars and accessories to the judgement of the critic and for the instruction of the public. Owing to the great demand for space the show is to be divided, part of the exhibits being displayed at Olympia, Kensington, and part at the White City, Shepherd's Bush. The one ticket admits to both portions, and arrangements have been made to convey visitors from the one to the other. During the last few weeks and this week our advertisement columns have contained a number of notices by leading manufacturers, the perusal of which will have assisted readers to appreciate some of the new developments; they will be more fully described in the article to be published next week. The show will close on Saturday, November 11th.

PROFESSOR JOHN CLELAND, M.D., LL.D., F.R.S.

FORMER students of Professor John Cleland in the University of Glasgow will be interested to read a letter received by Professor James Battersby, one of the honorary secretaries of the Section of Anatomy at the Annual Meeting of the British Medical Association in Glasgow. The proceedings of this Section are reported in the *JOURNAL* this week. At the opening of the meeting, on the suggestion of the President Professor Alexander Macphail, a message was sent to Professor Cleland (now in his 88th year) expressing the esteem, high regard, and affection in which this veteran anatomist is held. His acknowledgement runs: "Please convey my most grateful thanks and hearty good wishes to the Anatomy Section of the British Medical Association. I can assure them that their kind messages are deeply appreciated by me. To those who are old students of my own I would add my most affectionate remembrances and appreciation of their regard."

THE COMMERCIAL DISINFECTION OF WOOL AND HAIR.

THE Advisory Committee on Anthrax, set up by the International Labour Organization, will meet in London on December 5th, under the chairmanship of Sir William Middelbroek, M.P. The Governments of Belgium, France, Germany, India, Italy, Japan, South Africa, Spain, and Sweden will be represented. The International Labour Organization, though maintained out of the funds of the League, was established not by the covenant but by the special section of the peace treaties; Germany, for example, has been a member of the Organization from the first. The United States has not joined, and will not be officially represented at the meeting in London, but it is sending the chief of its Biochemic Division of the Bureau of Animal Industry to act in an unofficial capacity. The original proposal of the International Labour Organization was for disinfection of wool at the ports, under the supervision of an international commission. It was objected, however, that certain processes of disinfection were of doubtful efficacy and might have injurious effects on the quality of the wool, and that anthrax spores were frequently carried in hides and skins, which, strangely enough, had not been included in the scope of the proposals. The committee which is to meet in London is to examine the whole question and make proposals. An illustrated account of the fine

station for the disinfection of wool and hair erected on a site adjoining the wool warehouses of the Mersey Docks and Harbour Board of Liverpool was published in this JOURNAL of December 3rd, 1921 (p. 952).

THE GENERAL PRACTITIONER'S SHARE IN MEDICAL RESEARCH.

THE latest convert to Sir James Mackenzie's teaching that the greatest need of medicine to-day is to seek out the beginnings of disease is Lord Riddell, who has given a very understanding account of the doctrine in *John o' London's Weekly* (October 21st). The matter, he says, may be put "in a nutshell. The ordinary method of investigation is to begin with the disease and work back to find the cause. Sir James says that the proper method is to watch for the cause and work up to the disease. Thus, instead of travelling from B (the disease) to A (the cause), you must reverse the order and travel from A (the cause) to B (the disease). This sounds practical common sense." But is not this to ask of medicine more than is asked of even the exacter sciences? Whether it be the chemist observing an unexpected precipitate, or an astronomer measuring the variability of a star, the new phenomenon must be accurately recorded and verified before its explanation is sought, the observation of the effect must precede the search for its cause, the existence of a problem must come before its solution can be considered. These are commonplaces to which we have no doubt Sir James Mackenzie would subscribe, but their application to medicine presents special difficulties. It might be a very good thing if everyone went periodically to his doctor to be vetted, but, as things are, few go until they feel ill, and, as experience proves, if the disease be chronic, only too often when the mischief is done. But this is not always the case, and the reply of the St. Andrews school will be something to this effect: "Granted all that, there are still a good many instances in which people seek advice for some slight and, as they hope, transient feeling of indisposition, or because, without any definite symptoms they can recognize, they feel below par: that may give a chance to investigate disease before the occurrence of any structural change in any organ. Or again, an acute febrile attack, such as may be caused by catarrh of the upper respiratory passages, of no great importance in itself, may give the doctor his opportunity." If this be so, then the application of what we may call the St. Andrews doctrine falls to the general practitioner, who alone can follow in Sir James Mackenzie's footsteps. He is in the best position to observe the beginnings of disease, and he alone can follow up patients and observe the outcome of complaints. The task as we have briefly stated it is very wide, and there is the risk of a diffusion of energy, the besetting difficulty of the general practitioner who desires to work in the scientific spirit. All difficulties, however, may be overcome if the public learns to take sufficient interest, and it is significant that a journalist so experienced as Lord Riddell should, by publishing the article to which we are referring, show that he believes the public can be interested.

VIRUS DISEASES IN PLANTS AND ANIMALS.

At a meeting of the Association of Economic Biologists on October 13th at South Kensington a discussion took place on virus diseases in plants and in animals and man. Dr. E. J. Butler, of the Imperial Bureau of Mycology, who spoke on the subject in relation to plants, said that the first demonstration that disease could be caused by a filtrable virus was given by Iwanowski in 1892. This related to the mosaic disease of tobacco, a disease now known in nearly a hundred species of plants. Other diseases, such as peach-yellow, were probably caused by similar agents, though the filtered juice was not infective. The eliot method of transmission of virus diseases in plants was by insects, and infection might be hereditary in the insect transmitter. Mere contact would not cause infection. The causal agents were believed to be

living organisms, and large amoebiform corpuscles or smaller granules had been found by several recent investigators in infected cells. The subject of virus diseases in animals and man was dealt with by Dr. J. A. Arkwright, of the Lister Institute (now, happily, recovered from typhus), who said that the chief points of interest common to plant and animal virus diseases concerned the nature and properties of the virus; the means of transmission—that is to say, the "carriers" and insect vectors; the measures of prevention, such as breeding or selection, and isolation or destruction; and perhaps also the concentration of the virus in certain special tissue cells. About fifty animal virus diseases had been described. They might be placed, roughly, in four categories. There were those in which the virus was visible, not filtrable, and not cultivated; those in which it was probably visible, filtrable, and cultivated; those in which it was possibly in some cases visible in the tissues, filtrable, and not cultivated; and, finally, those in which it was filtrable and very resistant. An example of the first of these categories was Rickettsia; of the second pleuro-pneumonia of cattle and poliomyelitis; in the third foot-and-mouth disease and vaccinia; and in the fourth fowl-pox and infectious pneumonia of horses. In their general properties most of the viruses did not differ much from bacteria, though some showed great resistance to drying, glycerin, and heat. The smallest clearly visible and largest filtrable particles were of the same order of size—about 0.2 micron—and the differentiation of colloidal particles of this order by means of the microscope was often extremely difficult and required attention rather to the arrangement and range of size and shape than to the appearance of the individual particles. Dr. Arkwright regarded it as theoretically possible on certain analogies that an enzyme might be the cause of infectious disease.

"KAFFIR COW-POX."

THE *Times* of October 17th published the following brief news note: "Kaffir cow-pox has reappeared in some of the northern towns of Jamaica. It has assumed a more serious aspect than the outbreak of last year, several deaths having been recorded." No doubt this refers to mild or modified small-pox, such as has occurred in many parts of the world in recent years, but it would require local knowledge to explain how the term "Kaffir" reached Jamaica in that connexion. In a letter which we published on August 12th (p. 283) Dr. R. U. Moffat stated that the name "Kaffir pox" was brought into use for small-pox in Kimberley forty years ago because the place then depended for food and fuel on bullock-wagon transport, and was threatened with starvation owing to the alarm of small-pox stopping the traffic. As we have urged, and as the Ministry of Health has advocated in a leaflet on mild small-pox—commented on by us on August 19th (p. 316)—where an outbreak is regarded as variolous it ought to be called small-pox qualified by an adjective such as mild or modified. Terms like alastrim, amaas, Kaffir, and so forth only lead to confusion. It may be pointed out that the statement in the *Times* note about Kaffir cow-pox being more severe in type in Jamaica than in the previous year rather agrees with an observation made by Dr. Monckton Copeman in his report on such an outbreak in England, published by the Ministry of Health in its volume for 1919-20. In the course of his early visits Dr. Copeman had expressed the opinion that "as the disease gradually became more acclimatized" it would tend to "approach more nearly to the type of small-pox as ordinarily met with in this country." That is what happened; in the later cases the severity of the symptoms was markedly greater. No such development, however, is recorded in many outbreaks, but in our last issue (p. 775) Dr. Wanklyn gave a warning as to the high fatality rate of the disease in and around London, notwithstanding that the outbreak included cases so mild as to be mistaken for chicken-pox. To-day we publish (p. 819) Dr. Hamer's report

to the London County Council on groups of cases in the outbreak. He points out the striking contrast between the 700 cases with one death in the Midlands and the North during the present year, and the five deaths in 19 cases in and around London between July 26th and October 13th. He emphasizes also Dr. Wanklyn's warning as to the need for prompt recognition at the earliest possible stage of the disease. The warning should be heeded. We have had comparatively little small-pox, and hardly any of it severe, for years past, but it may come at any time like a thief in the night, and may readily spread in a population now so largely unprotected against its assault.

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

At the fourth congress of the Far Eastern Association of Tropical Medicine which was held at Weltevreden, Java, in August, 1921, a proposal was made on behalf of the Governments of the Straits Settlements and Federated Malay States by their delegate, Dr. A. E. Horn, that the next meeting of the Association should be held in Malaya in 1923, was adopted and Dr. A. E. Horn was chosen president; Dr. A. L. Hoops and R. Dowden were elected vice-presidents for the Straits Settlements and Federated Malay States respectively; and Dr. Schaff honorary secretary for Malaya. It has been decided to hold the meeting at Singapore from September 3rd to 17th, 1923. The first week of this period will be devoted to scientific discussions, and the following week to excursions to points of medical and sanitary interest throughout Malaya. The Governments of the Straits Settlements and Federated Malay States recognize the important work done by the Association and are contributing a considerable sum towards the expenses. The object is to promote the science and art of tropical medicine in the Far East. For this purpose the Association endeavours to unite into one compact organization the medical profession of the Far East, for the growth and diffusion of medical knowledge; to promote friendly international intercourse among physicians; to elevate the standard of medical education; to enlighten and direct public opinion in regard to the problems of hygiene; to form habits which may conduce to the prevention of disease among the native population; and to present to the world the results of such scientific observations. The membership of the Association is open to the members of all duly constituted, regularly organized medical societies within the field of the organization, and all medical officials in the civil, military, naval, or other organized services of Governments within their territories. Those who wish to submit papers are asked to communicate as soon as possible with the honorary secretary.

"THE NEW MEAL POKE."

It is nearly twenty years since a volume called the *Meal Poke* was published to help a students' bazaar in Dundee. The *New Meal Poke* has now been issued with a similar object; in this instance it is to help a bazaar to be held, in the words of the Chancellor, Earl Haig, to obtain money "to provide more suitable opportunities for our Dundee students to obtain proper health-giving relaxation from the classroom and study. The rapid growth in the number of students at the College makes the matter an urgent one." The new volume has been prepared for the Students' Representative Council by a small committee, and we observe that the address to the friendly reader on behalf of the Dundee Committee of the Students' Representative Council is signed by Dr. R. C. Buist and Mr. E. O'Brien. The name "meal poke" is, if we may say so without presumption, something of a misnomer, for a poke of meal consists only of one sort of thing—meal—whereas this poke contains many sorts of things, from a poem by Mr. Hardy to an essay by Mr. E. V. Lucas, from a reminiscence by Sir J. M. Barrie to a song by Dr. David Rorie, about which we can venture no opinion until we have heard him sing it. Many of the other contributions to the text attain a high order of merit; there

are several translations, one from the Provençal of Count William of Poitiers, by Professor A. Blyth Webster, which gives some idea to those unacquainted with that dialect of what was accomplished in it. The contributions, indeed, are evidence of how well the Muses are cherished at Dundee and St. Andrews, and the illustrations also reach a high order of merit; Dr. R. C. Buist has written a sonnet for the frontispiece—"Lifelines," by Alice Grieve. The volume has been produced in excellent style by Messrs. George E. Findlay, Victoria Printing Works, 6, Victoria Road, Dundee, and the net price is half a crown. The postage would seem to be 4½d. There is also an edition du luxe, limited to 200 copies, but the price of it is not stated.

THE NEW MINISTRY.

THE resignation of Mr. Lloyd George's Government having been due to the action of the Conservative party the new Ministry, which took office on October 24th, is purely Conservative, but of the 17 principal members 9 were in the last Ministry. The immediate duty of Mr. Bonar Law's Cabinet will be to get the new Parliament together in time to pass the Irish Bill, and as the relative strength with which the several parties will return from the country can less than ever be forecast, there is a certain unreality in discussing either its programme or its members. With regard to the first, Mr. Bonar Law has said that he will be guided by the belief that "what the country needs is tranquillity, freedom from adventures and commitments, both at home and abroad." Sir Arthur Griffith-Boscawen, who was Minister of Agriculture in the last administration, becomes Minister of Health in succession to Sir Alfred Mond, who replaced Dr. Addison early last year. Sir Alfred Mond has done good work at the Ministry of Health, and in particular showed sound judgement in meeting the demands for economy, and courage in resisting proposals to hamper important health services. In taking leave of the Ministry Sir Alfred Mond circulated the following note for the information of all officers of the Ministry: "On leaving the Ministry of Health I desire to express my high appreciation of the work of the staff. The questions with which they have to deal touch the lives of the people at more points than the work of any other Department of State, and are of the greatest social importance. There is no warmer praise than to say of them, as I do, that their efficiency and sense of duty is on a level with the high ideals underlying the work of the Ministry. I wish you to convey to them my gratitude for their loyalty to me in work which was very near my heart, and my hope that my successors will be as ably supported in carrying it on under happier financial auspices than I enjoyed."

THE Schorstein memorial lecture at the London Hospital Medical College will be delivered by Dr. Percy Kidd in the anatomical theatre of the College on Wednesday, November 8th, at 4 p.m. The subject selected for the lecture is "Forty years in the history of tuberculosis."

THE Huxley lecture on evolutionary tendencies in man's body will be given in the large lecture theatre of the Charing Cross Hospital Medical School by Sir Arthur Keith, M.D., F.R.S., on Wednesday, November 8th, at 3 p.m. The chair will be taken by Dr. William Hunter, C.B. Admission is free, without ticket.

THE annual medical service of the Guild of St. Luke was held in St. Paul's Cathedral on the evening of St. Luke's Day, Wednesday, October 18th. Prayers were intoned by the Rev. W. J. Foxwell, and the musical portion of the service was rendered by the organist and choir of St. Mary Abbott's, Kensington. A new tune, composed by the Rev. H. Kirkland-Whittaker, M.D., secretary of the Guild, was used for the hymn, "Thou to whom the sick and dying." Dr. St. Aubyn-Farrer and the Rev. Dr. Kirkland-Whittaker read the first and second lessons respectively. After the sermon by the Rev. Lord Victor Seymour there was a procession.

WINTERING ABROAD.

THE FRENCH RIVIERA.

To winter abroad on the ground of health is not an entirely modern practice. To do so seems to have been by no means a rare prescription nearly or quite a century ago, among places then in vogue being Montpellier, not far from the western end of the Riviera, and Florence, close to the eastern end.

Their accommodation for strangers was considered satisfactory, and their climates more favourable to chest cases than those of English cities and villages. Also as the times went—travellers in those days were bolder and less exacting than now—they were considered to be easily reached.

Later on they lost their reputation in this connexion, but whether from recognition of their essential lack of climatic virtue, or owing to the opening up of the Riviera, it is difficult to say. In any case soon after the middle of last century the stretch of coast from Toulon to Genoa began to be identified in medical minds with "Wintering Abroad," and now for many years past the names of the principal towns on the "Côte d'Azur" have been nearly as familiar to frequenters of English railway stations as those of Blackpool and Brighton.

In Roman and mediæval days nearly all the existing Riviera health resorts were places of some importance, but when their present rôle commenced they were, with the exception of Toulon and Nice, little more than a string of fishing villages. Their development from this into their present condition was slow, and in some instances due to more or less fortuitous circumstances. Hyères, for instance—about the first place to become well known—owed its rise no doubt to its relative accessibility, it being close to Toulon, which was itself for some little time popular in this connexion, and always a naval station of importance. Nice, again, which came into the picture even earlier in the development of the Riviera as a whole, had the advantage of being already a cheerful garrison town. The name of the principal part of its sea front—the Promenade des Anglais—would in many places be merely a compliment, but in Nice it marks the quarter in which the English colony first established itself.

In other cases the energizing factor was some accidental circumstance, such as that a particular view or site in its neighbourhood charmed some "personage," who thereon purchased ground, built himself a villa, and became a kind of collecting centre. This term "villa," it should be noted, is now occasionally used on the Riviera as it is in a suburb of London, but for the most part it preserves its original significance and indicates a large house surrounded by more or less extensive ornamental grounds.

Finally, there are towns that owe their rise to some medical man having deliberately picked them out as ideal places of residence for invalids, and his having "written them up" accordingly. The most notable instance of this is Mentone, which has recognized the fact by erecting a monument Henry Bennett.

THE LIE OF THE LAND.

The term "Riviera" (meaning "bank" or "shore") was formerly the correct geographical description of the northern coast of the Mediterranean from Nice to Spezia. Nowadays it is a popular phrase rather than an official term, and is often made to cover the whole coast between Spain and the peninsular portion of Italy. People less loose in their diction, and more practical in their ideas, speak of the Western Riviera, meaning all places between Cannes and Toulon (both included), but nothing nearer the Spanish coast; the Central Riviera, meaning the coast from Nice to Mentone; and the Eastern Riviera, meaning all places from the Italian frontier to a little beyond Genoa.

It is a coast with very numerous bays, but, since none of these is deep and the general run of the coast is from east to west, there is no great difference in the latitude of any of the towns and villages thereon. They are also alike in the fact that if the Mediterranean Sea could be emptied out it would be seen that they all lay on a ledge about one-third of the

way up the side of an enormously deep valley; likewise that this ledge, though always at much the same height above the bottom of the valley, varied a good deal in its breadth, and also in its level, in relation to the side of the valley above it. Similarly, if the Mediterranean, instead of being emptied out, were one day deepened by a few hundred feet, it would be found that, though the present bays still existed, they had been broken up at frequent intervals by creeks running right into the side of the valley.

Stress is laid on these facts because they account for the difference of the climate of the Riviera as a whole from that of any other southern health resort, and they are also of material importance when a preliminary choice has to be made between one place and another within its borders, either for treatment or residential purposes. Indeed, anyone who bears them in mind in relation to any town specially commended to him can, with the help of a large-scale map, decide for himself how far it is likely to meet his desires.

CHEATING THE CALENDAR.

The desires of those who imitate the swallows no doubt vary, but the primary aim is usually to cut winter out of the calendar. It is a common belief that this can be done by merely going south; or, in other words, that wintry conditions are simply a question of latitude. This is a mistake. Winter is more or less unpleasantly perceptible far below the limits of Southern Europe; indeed, as far south as beyond the Atlas Mountains in Northern Africa. In this hemisphere only within a few degrees of the equator is winter practically non-existent.

No doubt the Riviera owes something to its latitude, and a considerable something to factors such as its southern exposure, its proximity to the Mediterranean Sea, and the clarity of its atmosphere. But if this were all its climate would not materially differ from that of a host of places much farther south, or even from that of a considerable number in the United Kingdom itself; also the Riviera would have an only minor advantage over the two places mentioned at the beginning of this article, which lie almost precisely in the same latitude as Nice and Mentone.

What spells all the difference are the circumstances that have already been emphasized as points to remember—namely, that the Riviera lies practically on a ledge of ground on the side of a deep valley. As the length of the valley runs east and west its side above the ledge protects the latter more or less completely from the north. The narrower the ledge at the site of any given town or habitation, the lower its relative position to the bulwark above it, and the less the bulwark is cleft, the more hopeful is the prospect of him or her who aims at cutting out the winter.

The side of the valley at its Central Riviera and Eastern Riviera portion is formed by the Alps. To many people the latter term means nothing but Switzerland, but the Alps really run so much farther south, and without any very considerable diminution of their height, that in many places they form the very edge of the Mediterranean Sea.

The side of the valley at its other end—that is, on the Western Riviera—is formed mainly by what are known as the Esterel and Maure Mountains. Their geological connexions are not well defined; possibly they are an outcrop of the Cévennes or even of the great central Massif of France. They are lower than the Alps, and extend over a relatively very narrow band of country; consequently they are somewhat less effectual as bulwarks.

The width of the ledge varies constantly from end to end. Throughout it is of such limits that there is a front and a back to all towns and villages, part of the houses lying nearly at sea-level, and others either on foothills or on mountain spurs. In some areas it is so narrow that the mountains nearly push the habitations into the sea.

The clefts that have been mentioned always let through a certain amount of northerly air, as they form subsidiary valleys at right angles to the sea. In a minor degree they account for the climatic differences between town and town, and fully for the fact that on any given day one quarter of a town may be materially colder than another. This is why wise people on the Riviera always go about armed with a wrap of some kind. A further reason for the same precaution is that owing to the heat of the sun promenaders may feel cold if they have to go home along a street shaded by high houses on both sides.

But the most important effect of the topography of the Riviera still remains to be mentioned. Despite the fact that it lies on the edge of the sea, the climate of the Riviera is to

* Amongst other descriptions of the Riviera are Riviera levante and Riviera ponente; also the "French Riviera" and the "Italian Riviera." The two former terms are now quite out of date, but at one time were official. They mean respectively the Riviera from Nice to Genoa (Riviera ponente) and the Riviera from Genoa to Spezia (Riviera levante). The other two terms explain themselves—the French Riviera covering everything from Toulon to Mentone, and the Italian Riviera all Riviera resorts under Italian jurisdiction.

be regarded as stimulative rather than as sedative. Its air, in short, is usually not sea air but dry mountain air.

So many authorities have discussed the meteorology of the Riviera that it is impossible to say who first pointed out this fact, but it is perhaps Samways of Montono who has done most towards clearing it up.* To summarize his observations briefly, it may be said that the Riviera receives most of its air much as does a room from an overhead ventilator. The mountains above the ledge deflect all wind from Northern Europe into the upper atmosphere; thence if it has been moving only slowly it drops to sea-level again as wind, at a varying distance from the point of deflection—that is to say, from the top of the bulwark. This is why the sea is often rough when there is no wind at all on shore, and also one reason why the atmospheric conditions at the front and in the high-lying areas of any given town are commonly appreciably different. But of course air does not reach the Riviera solely from the north. Easterly and westerly winds blow with fair frequency, and the extent to which they are felt varies in each place according to the degree to which the place is protected by spurs of mountain running seawards. The wind from the east is not a cold wind, but any marked wind on the Riviera is resented and the westerly wind, locally known as the "mistral," certainly has something of the irritating character of an east wind in the United Kingdom, though in other ways it is its converse.

The effect of all the various factors to which reference has been made could be reduced to figures, but it is better to refrain. To many people meteorological returns are Chinese, and even to those who deem themselves competent translators they are apt to be misleading unless unusually complete and studied with great care. It is so easy to forget that in respect of their reflection on human comfort and on human well-being the facts represented by meteorological data are much less important than are the interrelations of those facts. Even if unconsciously anyone who has ever spent any time on a snowed mountain must have become aware of this. Consequently everything that it is proposed to say on the subject of the Riviera climate other than has already been stated will be found in the paragraph headed "The Season."

One point may, however, conveniently be mentioned here. The meteorological data of the Riviera might easily be taken to spell dust, but in the writer's experience dust is not one of the troubles of the Riviera so far as its visitors are concerned. Wherever motor traffic is heavy there is bound to be more or less dust, so that the Riviera cannot be entirely free from it. But only on main roads is motor traffic over heavy, and in the neighbourhood of towns on the Riviera which have recovered from the war road surfaces are kept well tarred and in the towns themselves free road watering is practised. Likewise main roads are frequented only by people in carriages of one sort or another, and as a general rule the hotels and other buildings used by visitors are isolated from roads of all kinds by gardens.

CHOOSING A LOCALITY.

Practically every dweller on the Riviera, whether his stay be short or long, becomes either a keen advocate or a depreciator of the place of his stay. Likewise the number of possible places of residence is very large. There are at least twenty-five recognized resorts if all three Rivières be taken together, in addition to many others which do not seek fame, though often they equally well deserve it.

For this reason, as also from a desire to be perfectly neutral, it is intended to leave the task of differentiating between places to those individually interested in the question. Still, certain general observations are legitimate and will be helpful. The most completely developed towns, as also the largest, are Cannes, Nice, Monte Carlo, Mentone, and San Remo.

Cannes, though less well protected than some other places, has always been specially favoured by persons of everywhere recognized rank. It is becoming more democratic, but is still less of a town than a collection of scattered villas. Nice is the metropolis of the Riviera, and a place which in its very long history has never fallen from the position of a town of importance. It is specially favoured by the French and the Americans, and though by no means always warm is never so cold as to check the gaieties always in progress therein. Monte Carlo, which commonly reminds one of a stage setting, collects people of every class and of all means, and a considerable number of them do not frequent the place simply for gambling purposes. Mentone consists of two parts,

of which one—Mentone-Garavan—is very quiet and somewhat isolated. The other half, which is quite as well protected as any part of the Riviera other than Mentone-Garavan, is very much up to date and in "the season" very gay.

In regard to degrees of protection the towns on the Western Riviera are rather less favoured than those on the other two Rivières, more especially when the mistral is blowing. The spot where the protection is in all respects most complete is Garavan.

From the point of view of country walks, picnics, and hill climbing, those places lying at spots where the ledge which has been mentioned is narrow certainly have an advantage over others.

It has already been stated that the rise of some of the Riviera health resorts was due to fortuitous circumstances. It is a fact to be borne in mind when the choice of a place for a long residence is in question. A great many new places have come into existence in the last twenty years, and the success of some of them, as also of some of their elders, the writer has never been able to understand. If merely a short visit be in question the choice of a locality may safely depend on the view of any friend who claims to know the Riviera and whose opinion on most subjects is to be regarded as well balanced, since there is no part of the Riviera that has not strong attractions. But if a long stay be anticipated, or the visitor wishes to fix up a more or less permanent home, he should look into matters carefully himself. As already suggested, he can get a great deal of useful information merely by study of a large scale map, if he remembers the points of importance—the narrowness of the ledge, the height of the hills above it, the number of clefts or subsidiary points of exposure of the town in respect of the south, and the extent to which its bay (practically every resort is at the head of a large or small bay) is protected on the east and west by outlying spurs of the general bulwark. He can make his choice still better by camping at some hotel for a short time and running along the Riviera either in a car or even in a train. In this way he is likely not only to fix on a place which will realize his expectations, but may even prove a pioneer, since he may discover a spot which, although lying in a not specially well protected area happens to be itself very well protected owing to the conformation of the hills in its immediate proximity. Many more or less isolated villas owe their existence to some such circumstance. The same consideration also applies equally to different spots in one and the same town.

DWELLING PLACES.

People native to the Riviera commonly describe all others as "les étrangers," even when the nationality of the latter is French. Sometimes they distinguish them by speaking of "les résidents" when they mean villa dwellers and their like, or by applying the term "les bivernants" to those who live in hotels and pensions. The difference between the two classes, however, is rather elusive, since some villa dwellers occupy their Riviera homes throughout the year and others only for a few winter weeks. Correspondingly, many hotel sojourners, or true hibernants, return to the same rooms in the same hotels year after year and remain from beginning to end of the season.

The number of hotels is legion; they are, indeed, at the present time considerably in excess of usual requirements on the Western and Central Rivières, thanks to the fact that the Germans, who formerly bulked very largely on these, have disappeared, and that Russian visitors, though for different reasons, are now comparatively rare.

The general system at all the hotels is much the same. Most have small or large gardens attached, and all have lifts, central heating, electric lighting, and bathrooms. Commonly, too, running water, hot and cold, is supplied in the bedrooms, and there are either special bridge rooms or some equivalent arrangement. Few are keen on letting bedrooms only; they prefer to arrange terms "en pension"—that is, terms which cover sleeping accommodation and the three ordinary meals of the day. These are a breakfast of coffee, tea, or chocolate, with rolls and butter, served in the bedroom, an elaborate meal ready soon after midday, and a five- or six-course dinner about half-past seven in the evening.

In a way, therefore, it may be said that the Riviera hotels are less hotels than elaborate boarding houses. But it should be added that in respect of general accommodation and of good feeding arrangements they are in most cases superior to good seaside hotels in this country and always on a par with them. The same is true of their sanitary arrangements, and, at all

events at all places in the Central and Western Riviéras, the drinking water may be written down as safe. Besides ordinary first-class hotels there are, at several of the larger resorts, hotels which call themselves "do luxe"; they are an exact equivalent to such hotels as the Ritz or the Savoy in London. As for places calling themselves "pensions," the difference between them and the small hotels is not very marked. Usually, however, they do not keep night porters or care to receive visitors of irregular habits, or for less than a stay of a week or a fortnight, and the meals at all of them are of a less luxurious type than at the hotels, and are served at a fixed hour. Everywhere it is the custom to make up and supply gratis portable luncheons for those who wish to go out for the day.

It is difficult to make any precise statement regarding hotel charges, the chief reason being that the value of the franc is constantly varying. Also the number of francs asked for any given room is subject to alteration each year according to food and labour prices. Just before the beginning of each season the hotel proprietors arrange this question between themselves according to the class of the hotel concerned. Invariably, however, rooms facing the south are priced higher than those with other aspects. It is true that southerly rooms receive more sun than others, but the views from the windows are by no means always better.

The exact position of an hotel should always be ascertained before agreeing to stop in it for any length of time. Those practically on the edge of the sea have advantages, but are not desirable if accessible only from an entrance in a much-shaded street. Other things being equal, it is well to choose an hotel close to the centre of the town, but those at a distance from it often have the advantage of possessing such large and beautiful gardens that their guests if not strong are content to spend most of their time therein.

Likewise if the visitor's stay commences early in the season there should be a clear understanding as to what the charges will be at the height thereof. Last year there was a great outcry about the exorbitant prices demanded by Riviera hotel-keepers. The writer was never able to see that this was really justified; the prices were and always will be higher than pre-war prices, but English visitors, from whom almost exclusively the complaints came, forgot how little they were paying—thanks to the exchange—as compared with French visitors. Nor did they compare the prices they were paying on the Riviera with what they would have had to pay for like accommodation at health resorts and other towns in England. This year, we are told, the hotel tariffs on the Riviera have been considerably reduced.

If it be necessary to come down to exact figures and make a forecast as to the cost of a stay on the Riviera in the coming season it may be said that board and lodging at a good place will probably be obtainable for between twelve and twenty shillings a day.

A statement of the basis of this estimate may be useful. As the value of the franc shows no tendency to rise and food prices have not materially altered, last year's events are a fairly good guide. In that season the writer found rooms for several friends. Of these "A," a lady accustomed to life in a London "Working Ladies" club, paid 18 francs a day en pension in a "commercial" hotel. She came for a fortnight but remained six weeks. "B," a lady from an English village, paid 30 francs in a poorly situated but otherwise good hotel; "C," a widow of means, paid at first 40 and then 50 en pension in a first-class hotel on the sea-front and in the centre of the town. "D," a well-to-do family man, paid 40 francs right through the season for each of his party in a first-class hotel with magnificent grounds at some distance from the centre. "E," a wealthy bachelor, paid in a "luxe" hotel 90 francs en pension for a long stay, but had a room fitted as a bed-sitting room, a private bathroom, and the services of a good valet.

As for dwelling places other than hotels and pensions it is well to appreciate the terms commonly used in speaking of them; an "appartement" means a flat, whether it be large or small; a "pavilion" means a very small house which has probably at one time or another been the lodge of a large estate. A "chalet," a comparatively recent term, commonly indicates a moderate-sized house away from the centre of the town but standing in very limited grounds. A "villa" usually indicates a very large house of many rooms standing in a large garden. As, however, in the case of large houses in London, many villas are now being cut up into flats and part of their grounds used for building purposes. There are

also dwellings to which none of these terms are applied, but which are simply called by some fancy term, such as "The Nest" or "The Outlook." Their exact character should always be ascertained as some of them tend to be jerry-built.

All these various habitations can at times be taken unfurnished and on long leases; not infrequently too they can be purchased outright. In the latter case the purchase price sometimes represents a very low rental value. As a rule, however, they are let furnished and only for the season. In this case they must, according to local laws in most towns, be really completely furnished and be thoroughly habitable, such things as linen and table cutlery being provided. Naturally prices vary greatly, but an average price for an "appartement" of, say, two sitting rooms, three bedrooms, a kitchen, hall, and lavatory, would be between 4,000 and 5,000 francs for the season. If a bathroom be provided it usually means an additional 400 or 500 francs. A "pavilion" may sometimes be got for less than 2,000 francs, while the rentals of "chalets" and "villas" may be taken to run from 6,000 francs upwards.

The season from a house-renting point of view means in most places from October 15th to May 15th—that is to say, for a period of seven months. But proprietors are usually willing to extend the lease from its initial term for any additional number of weeks desired for a very moderate figure. It may also be said in favour of proprietors—in France a much-hated class—that on the Riviera they are not sufficiently sophisticated for heavy claims for damaged furniture, etc., to be common, as in England. Also, too, the ceremonies connected with habitation renting are relatively both simple and inexpensive. The agent makes out the necessary agreement, and commonly it is a very brief document, since generally French law is not elaborate and all agreements are interpreted according to local custom.

Even more than in the case of hotels it is desirable for the prospective renter to ascertain the exact position of the residence. It is true that more or less distant houses often have the advantage of exceptionally beautiful surroundings or of being specially well protected from weather conditions; but it is also true that the greater the distance from the centre of the town the greater the possible difficulty of house-keeping. Small "baker" and other like shops are usually to be found in the neighbourhood of any considerable collection of villas, but the larger tradesmen have not yet resumed their former practice of sending round for orders. It should also be ascertained whether any habitation that seems otherwise desirable has either an air space, if not a definite cellarage, or a cemented foundation. If neither, it may prove cold, despite the usual dryness of the soil. The furnishing of dwellings, though always complete, is not always very smart or of such a comfortable kind in the matter of chairs as those to be found in English private houses. All visitors, whether residents or hivernants, pay nowadays a local tax, which is devoted by law to improvement of the amenities of the place. The sum varies, but is never enough to make any difference in the general expenses of a winter outing. Except for this English people who take houses merely for the season escape all "direct" French taxation.

"THE SEASON."

The term "Season" from the house agent's point of view has already been defined, but it may be useful to add that he always expects—and commonly not in vain—to have disposed of at least two-thirds of the habitations on his books at least six months before "next season" will commence.

"The Season" in other connexions is somewhat less definite. At most places there are hotels that are ready for visitors all the year round, but the majority do not open until October is well under way and begin to close at the end of April. At some, indeed, the season is much shorter, not beginning until about Christmas time. These usually are "de luxe" hotels, catering solely for pleasure seekers of large means. There are also a few first-class hotels which habitually prolong their seasons well into June.

The reason for these differences is rather obscure; one factor, however, is that "les hivernants" are capricious in their habits; masses of them sometimes suddenly leave in order to get home for Easter, "the holidays," or for a big social or political event. Another is that many Riviera hotel-keepers have season hotels elsewhere, and if for some reason their Riviera hotel be not very full they prefer to close down early and "repose" themselves and their staffs before starting a summer season elsewhere.

A third meaning of "Season" relates to public festivities, such as balls, battles of flowers, races, and the like. These commonly start some time in December, and end with April. Croquet clubs close relatively early, last feet and the sun destroy their lawns, but tennis, bridge, informal dancing, and boat sailing survive much longer.

Finally, the term "Season" should also be defined from the point of view of calendar and climate. Taking all the four calendar seasons together, the general character of the climate is indicated by the flora of the locality. It is sub-tropical throughout; in other words, apart from flowers of every kind, the palm, the agave, the pomegranate, the prickly pear, the banana, the orange tree, and the bamboo all flourish; lizards and the tree frog are common, and in some places the growing of lemons is a staple industry. Such flora is in this country regarded as of a hothouse kind.

The Riviera climate is not, however, of the conservatory kind, since the air, being mainly of mountain origin, is distinctly on the dry side instead of humid. Nor should the term "subtropical" lead anybody to suppose that all the calendar seasons of the temperate zone in which England lies are not well represented. At times, though frost is rare, it is quite cold out of the sun and as soon as the sun has set; and occasionally, though this is by way of being a great ovent, there is snow on the southern side of the Riviera's bulwark. There is also, unlikely for the country, usually plenty of rain, but also, luckily for the "hivernant," rainy days are few. When it rains it rains hard and has done with it. A related dissimilitude is that the air is always clear—that is, there is no mist and no fog—and clouds are few. Those who have to remain in England may, however, console themselves to this extent: when the English newspapers are talking of bad weather the Riviera press is very likely doing likewise. The "hivernant" expects nothing but brilliant skies and thoroughly genial air, and if during any given period of twenty-four hours neither condition exists his indignation is great. Usually, however, the home-stayer's envy is thoroughly justified, an ordinary Riviera October, November, and December being like a fine autumn or fair spring in England; January, February, and March like a good English summer; April, May, and June like a hot English summer. Of July, August, and September the writer cannot speak from personal experience, but he understands that the two earlier of these months are usually too hot to be enjoyed by most English people.

People who go to the Riviera either for definite health reasons or merely to avoid fog, mist, chronic rain, absence of sun, and possibly sleet and snow, should start if possible before the end of the autumn, and should not move away until more or less summer-like conditions in England seem well established. If free agents, it is folly for them to return home just in time for an Easter blizzard or a belated winter.

SUMMER MOUNTAIN RESORTS.

There is indeed no positive reason why they should leave the Riviera at all. A good many "residents" do, in fact, remain all the year round or merely spend a few weeks during July and August at one or other of the small summer resorts in the mountains close at hand. Of these there are already a good many, and others are being annually opened up thanks to the introduction of motor transport. In altitude they vary between, say, 1,200 and 5,000 feet.*

The opening up of the "Route des Alpes" by the P.L.M. Railway Company has also rendered pleasantly accessible, to those wishing to leave the Riviera during the hottest period in summer, the many delightful little villages situated high up in the mountainous hinterland; further, an excellent means of travelling to such famous historical towns and watering places as Briançon, Uriage, Grenoble, Chambéry, Aix-les-Bains (also well known as a winter sports centre), Annecy, St. Gervais, Chamonix-Mont Blanc (France's premier winter sports centre), Thonon, and Evian. The trip can be made in the well-appointed P.L.M. motor cars, which, starting from Nice, wind through the French Alps to Evian-les-Bains, overlooking the Lake of Geneva. The "route" has been skillfully planned so that the most beautiful and impressive scenery which the French Alps boast may be seen by the travellers. The trip is divided into six easy stages, each of one day's duration, which may be taken independently; opportunity is thus afforded to those wishing to spend a few days or a

season at any of the well-known towns and watering places already mentioned linked up by the "route," or at any of the picturesque little mountain villages which are touched. The highest mountain roads are used, some of the "cols" traversed being over 5,000 feet high.

There are also "hivernants" who do the same, or vary proceedings by a visit to some hydropathic town such as Uriage-les-Bains, or the more expensive but hardly more fashionable Aix-les-Bains, both in Savoy. It is also a fact that several Riviera resorts have a summer as well as a winter clientèle, the former coming down for the sea bathing, though they include few English. On the whole, therefore, it seems safe to conclude that though it is the fashion to go away, life on the Riviera must be livable even in the hottest weeks of the year.

SOCIAL CONDITIONS.

In the last ten years social conditions have changed considerably on the Riviera. Formerly certain towns were visited almost exclusively by invalids, while others were regarded mainly as pleasure resorts. Nowadays, though there are many invalids and convalescents to be found everywhere, all places alike make a point of organizing amusements of one kind and another. Naturally, however, these are better developed in the older settlements than in the new that keep springing up year by year. Such enterprises take the form of tennis clubs, croquet lawns, golf links, bridge clubs, book clubs, thés dantsants, balls, char-a-banc motoring, and occasional horse races, motor boat and sailing boat competitions, aviation meetings, battles of flowers, and the like. Everywhere there are churches of various denominations, and, since most people go in for picnicking and walking, the hill and mountain paths are well maintained and provided with sign-posts. Also in all the larger towns there are casinos providing theatrical and operatic performances, ball rooms and bands, and opportunities for losing money at "la bonolo" and other gambling games. A certain number of people go in for sea fishing, and for these who stay late in the season there are ample sea-bathing facilities. Also at all times of the year amateur and professional artists are everywhere to be seen.

In matters of dress there are people who continually change their costumes during the day, and others who are never seen except in the weirdest and apparently never altered apparel. At the hotels and casinos in the evening dinner jackets, and the equivalent feminine costumes, are invariably worn.

The Riviera is, in short, just like the west end of any metropolis, but spread over 200 kilometres of country instead of over a few square miles—a locality where everyone, for the most part, pays his money and makes his own choice of the why, when, and how. There are people who live such retired lives that they are never seen anywhere but perhaps in a church, and others who go in for every form of amusement and become rapidly known by sight even to quite temporary "hivernants."

Touch is maintained with the outside world by means of telegrams posted up at frequent intervals during the day at newspaper offices and outside banks, and by the London and other newspapers which arrive the day after their publication. But there are few or no reference libraries, and this is a great handicap to those whose preferred occupations are mainly intellectual. They can, however, if they please, occupy themselves in topographical study, in which direction, as also in those of ethnography and folk-lore, there are great temptations all along the Riviera.

Finally, to revert for a moment to the matter of dress, two quite common mistakes should be avoided. The one is thinking that a visitor who wishes to take part in everything that is going on will be comfortable if he arrives with the nothing but a golfing outfit; the other is thinking that the Riviera is at all times so warm that the lightest summer clothing will suffice. Those who wear more or less warm underclothing at home should not abandon it, and a light wrap and a warm coat are always desirable, even if eventually the latter be only used while travelling.

Riviera society is remarkably mixed, and is less divided up by questions of means, occupation, and origin than is "society" by questions of means, occupation, and origin than is "society" elsewhere. A fair number of people keep motor cars, but their possession, though sometimes envied, does not, as in some places, confer any social status, and is not on the whole especially desirable. There are plenty of other means of getting about, and in the "Season," at any rate, the Riviera is not an ideal place for motoring, despite the care with which the roads are maintained.

* Among those at present best known are St. Martin Vesubie, alt. 3,200 ft.; Vence, alt. 1,100; Alos, alt. 4,700; Belvédère, alt. 2,600; Berthemont-les-Bains, alt. 2,550; Beaufort, alt. 3,920; Annecy, alt. 2,200; Beuil, alt. 4,000; Villars-Colmar, alt. 3,800; Peira Cava, alt. 5,100.

standing point is that there is very little tendency to fall into groups according to the amusements chiefly attracting them, and residents commonly do the same and frequently have home occupations, or are keen on gardening and the like; so beyond, perhaps a few formal tea parties at their own houses, they trust to luck for meeting their social acquaintances elsewhere. Nevertheless there is much real friendliness among habitual Riviera dwellers, whether hivernants or residents, and it does not lack exhibition when the need arises. In such a community it is inevitable that there should always be plenty of material for gossip and an infinity of stories about people on the Riviera, both alive and dead, are always current. But it can also be said that, even though such stories be known to be true, the tendency of the Riviera is to take everyone exactly as they themselves find him or her, so in the long run neither gossip nor stories do anyone any harm.

EXPENSES.

Many English people buy all the francs they think they are likely to require before leaving the United Kingdom. Such people add somewhat to their immediate cares and are just as likely to lose as gain by the transaction. Banks are very numerous on the Riviera and most of them are willing to cash at sight English cheques from almost anybody.

The normal value of a franc is slightly under tenpence, but for the last three years this value has never been more than fivepence, and often not much more than fourpence. The value varies both in London and abroad, not only every day but several times a day. The price one may have to pay for any given number of francs may be much lower next week than on any given "to-day"; on the other hand it may be much higher, so the wisest course is merely to buy such a number of francs as suffice for the needs of the moment. As for the future the only thing that can be said with assurance is that the value of a franc is unlikely to rise in the coming season above its average value since the armistice. Consequently life on the Riviera during the coming season will be relatively inexpensive for English people and dear for their French comrades, as also for those who "bought forward" a long time ago.

The price of an ordinary first-class ticket to the Riviera is at the present moment £8 10s., and £13 8s. return. The price varies each month, the companies fixing it according to the rate of exchange prevailing through the preceding month. It is not, however, essential to travel first-class; trains having second-class carriages reach the Riviera as fast as those limited to first-class passengers. The journey from London to, say, Mentone (the farthest point of importance on the French Riviera) can be comfortably accomplished in just under thirty hours. There are also second-class carriages which the traveller need not quit between Calais and the final destination. To the particular train in question a restaurant is attached between Calais and Paris, and at Paris and at various stations afterwards luncheon baskets are brought to the through carriages. To all other Riviera-bound trains restaurant cars are attached practically throughout the whole journey, and it is said that in the coming season they will be so attached to the "through" train from Calais. Sleeping accommodation on the trains can be obtained by those who require it, provided they are travelling first-class. The principal difference, it may be noted, between a "conquette" carriage and a "wagon-lit" is that the latter is provided with toilet accommodation and ordinary bedclothing and that the former is not.

There are also the luxurious *lits-salon compartments*; the *lits-salon "ordinaires,"* a compartment containing three couches side by side, and the *lits-salon "avec draps,"* a compartment containing two couches with sheets; both of these compartments are provided with toilet accommodation and are well ventilated.

It is perfectly easy to reach the Riviera comfortably without knowing a word of any language except one's own, and when there is knowledge of French or Italian is of no particular advantage unless one starts housekeeping.

Most of the servants obtainable—and any house agent can commonly provide them—are Italians. A few will do nothing but some special form of work, but most are competent cooks and ready to take on any work that may be required. Their wages run from 100 to 200 francs a month, and if treated on patriarchal lines they commonly prove loyal and honest servants; still they should be carefully observed before the latter conclusion is drawn in respect of them. They usually know more or less French, sometimes a little English, and in

any case a means of mutual comprehension is usually rapidly established between servant and mistress.

The prices of food, electricity, gas, and coal are considerably above English prices. But such difference is at present fully outweighed by the abnormal cheapness of the franc. A servant, by the by, should not necessarily be written down as dishonest because when sent marketing she returns her expenditure at slightly more than the sum at which the mistress herself might possibly have obtained the same goods.

SOURCES OF INFORMATION.

The intention of this article has been to give a general idea of what life on the Riviera is like. Those who have a stay there definitely in view can obtain detailed information from (1) the Paris-Lyons-Mediterranean Railway Company, 179, Piccadilly, London, W.1; or (2) the Office Français du Tourisme, 56, Haymarket, London, S.W.1. In nearly all French towns which desire to attract strangers there is a society which lays itself out to supply information; their titles vary, but a letter addressed to the Secretary of the Syndicat d'Initiative will reach the desired destination. In most cases, however, the information obtained from one of the first two sources indicated will suffice, especially in the matter of getting the names of hotels, house agents, and the like. In regard to engaging rooms the traveller must of course communicate direct with the hotel keeper.

By way of concluding the whole matter it may be noted that the essential differences between Riviera resorts and those either on the shores bordering other parts of the Mediterranean or on islands in it are the greater accessibility of the Riviera resorts and the mountain character of their atmosphere. A similarly brief comparison between the Riviera and mountain resorts in Switzerland is more difficult. The main points are: (1) that a visitor cannot count on typical Swiss winter conditions unless he goes to a place at least 4,000 feet up, nor can he expect them to last more than about ten weeks; (2) that outdoor attractions are small unless the individual is sufficiently young to take an active part in winter sports; (3) when young persons are in question there is so much temptation towards exercise—skating, skiing, or tobogganing by day, and dancing and parlour gymkhanas at night—that they are very liable to overdo things. On the Riviera there is plenty of opening for exercise and nearly everybody does as a matter of fact take a good deal of exercise in the daytime, but after sundown the general tendency is to rest, except, perhaps, for an occasional visit to a casino or to some dancing place.

SMALL-POX IN LONDON.

The following report from the county medical officer on recent outbreaks of small-pox in and around London was presented to the London County Council at its meeting on October 24th:

"During the period July 26th to October 13th, 1922, 19 cases of small-pox occurred in and around London, including one case which was not discovered until the patient had completely recovered, and was therefore not included in the list of notified cases. This series of cases may be classified into two main groups with the addition of one isolated case, as follows:

"(a) This outbreak originated in Stepney in the person of a youth, aged 16, who developed a rash, which was diagnosed as chicken-pox, on July 4th, 1922. After remaining in bed for four days he assisted his mother in a shop on the premises, serving refreshments and tobacco. He infected six persons with small-pox, four of whom lived in Stepney, including one who developed his illness in Southend-on-Sea, and two in West Ham; one of the latter worked in the infected area whilst the other traversed the neighbourhood daily on her way to work. Four additional cases occurred among the contacts of the six patients infected by the original case, and with these the outbreak terminated, the last case having occurred on August 12th. Of the eleven cases comprising this outbreak, two died, and two others developed a severe type of illness; the remainder suffered from more or less mild attacks. Two of the patients had never been vaccinated and of those one died; in seven cases, whose ages ranged from 16 to 38 years, there was no record of vaccination since infancy, and one of these also proved fatal; the remaining two had been vaccinated since infancy and their illness was of a mild character.

"(b) This group of cases appears to have originated in Dartford, where three persons were removed to hospital from the same address on September 25th, suffering from small-pox.

"Two of these patients had nearly recovered from a mild attack and a doctor was consulted in regard to the third, who died a few days later. The patient who died was aged 49 years, who died a few days later, his sister living in London and her child,

a girl aged 12 years, visited this woman at Dartford on September 23rd, after the rash had appeared. They returned to London the following day, and were vaccinated on September 27th, but too late to ward off the disease. They fell ill about October 3rd, and were removed to hospital from an address in Fulham on October 5th. The child's attack is modified by vaccination, but the mother has since died. Two further cases, one in Dartford and one in Bexley, have since occurred among the contacts.

(c) An isolated fatal case of small-pox in Bclmal Green was notified, and removed to hospital on September 22th. The source of infection was not traced.

"It will be noted that unrecognized cases were responsible for both groups of cases (a) and (b), thus emphasizing the need for prompt recognition of the disease in the earliest possible stage. In this connexion it is appropriate to mention that the Council places at the disposal of medical officers of health and medical practitioners in London the services of its expert small-pox consultant, who is available at all times to give assistance in diagnosis.

"The fatality rate of small-pox in London during these outbreaks, in which 5 out of the 19 patients died, presents a striking contrast to that in the rest of the country, where over 700 cases have occurred, mainly in the Midlands and the North, during the present year, of which only one has proved fatal, according to the information at present available. This marked variation in the degree of mortality may be ascribed to divergent types of small-pox, the north country type having remained up to the present consistently mild.

"The danger of an epidemic of virulent small-pox in this country is accentuated by the unvaccinated condition of a large proportion of the population, especially young persons. Since the passing of the Vaccination Act, 1898, which provided for exemption from compulsory vaccination of an infant on the production of a certificate of 'conscientious' objection by the parent, the number of infants vaccinated throughout England and Wales has declined from 66.4 per cent. of births in 1899 to 39.5 per cent. in 1920. In pre-vaccination days the incidence of fatality of small-pox fell chiefly upon young children, and the accumulation within recent years of large numbers of young persons, deprived of the protection afforded by vaccination in infancy, may be fraught with grave consequences in the event of small-pox becoming prevalent."

England and Wales.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

THE annual dinner of the Society of Medical Officers of Health—now in its fifty-seventh year—was held at the Hotel Cecil on October 20th, with the president, Dr. T. Eustace Hill, in the chair. Owing to the present political crisis, the Minister of Health, Sir Alfred Mond, was unable to attend, and the principal toast—Prosperity to the Society—was proposed instead by the Dean of St. Paul's. In a brief speech Dean Inge remarked that medical men must sometimes feel that they were keeping alive persons whom Nature, with perhaps greater wisdom, might prefer to kill. There were diseases, such as haemophilia, which when once established in a family could not be brot out of it; the only way to eliminate such diseases was to discourage the propagation of stocks in which the defect existed. Preventive medicine, for whose triumphs he had great admiration, ought to lead on to eugenics. Those who knew most about these matters were aware that it would be long before knowledge was accurate enough to justify much legislation; but he hoped most medical men would agree that in the far future the science of eugenics must form an extremely important part of preventive medicine. The President, in his reply, mentioned some of the outstanding achievements of the public health service on behalf of the individual and the community. He said that the membership of the Society of Medical Officers of Health was increasing, and was now 1,700; the Society embraced all branches of the service and included seven specialist groups. Dr. Eustace Hill added a word of gratitude to the British Medical Association (represented at the dinner by Dr. Wallace Henry, Dr. Bolam, and Dr. Garstang) for its valued co-operation in obtaining security of tenure and improving the status and remuneration of the health service. The toast of the guests was proposed by the president, Dr. W. J. Howarth, and responded to by Sir

Herbert Nield, K.C., M.P., Sir Humphry Rolleston, K.C.B., President of the Royal College of Physicians of London, and Dr. R. A. Bolam, Chairman of Council of the British Medical Association. The health of the President was proposed by Dr. Sidney Barwise.

NATIONAL MILK CONFERENCE.

The National Milk Conference continued its sessions on October 17th and 18th at the London Guildhall. An account of the first day's proceedings appeared in our last issue (p. 771). Sir Alfred Mond, who was chairman on the second day, said that the aim of the legislation he had recently carried through was to induce the consumer to insist upon getting a better quality of milk. The new orders now under consideration had been purposely framed with a good deal of latitude, and he looked forward to ensuring, in addition to a very high standard grade, which must necessarily be expensive, a grade of milk free from manurial contamination and from tuberculous infection, which could be produced by any dairy farmer without great expense.

Bovine Tuberculosis and its Relation to Man.

Dr. A. Stanley Griffith, a member of the Bacteriology Department of the Medical Research Council, speaking on the frequency of bovine infection in the human subject, presented the following figures relating to surgical tuberculosis:

	Total number of positive cases.	Percentage of bovine infections.
Cervical gland...	154	46.5
Bone and joint...	476	18.3
Lymph...	126	51.8
Scrofuloderma...	52	38.4
Genito-urinary...	17	17.6

The percentage of bovine infection was highest in all these categories among children under 5 years of age, but adults were not exempt; 25 per cent. of the cervical-gland cases occurring in persons over 16 years of age were traceable to the bovine source. In pulmonary tuberculosis the human strain was the cause of infection almost to the exclusion of the bovine; this he attributed to the fact that, with few exceptions, the infection was of respiratory origin. He believed the bovine bacillus to be as virulent for man as the human; if its ravages seemed less evident, this was because its channel of entrance was restricted to the alimentary tract. Dr. Nathan Raw, M.P., maintained that a larger amount of tuberculous disease might be attributed to milk than Dr. Griffith had suggested. During the last twenty years, out of some ten thousand hospital patients suffering from tuberculosis who had come within his experience, he estimated that 2,100 were infected from milk. He had never found the human and the bovine bacilli both present in the human body. Dr. Stanley Griffith replied that in his series there were five cases in which bacilli both of the human and the bovine type were found. It would be dangerous to vaccinate cows with human bacilli to protect them from bovine tuberculosis; in some experimental cases he had found human tubercle bacilli living in the mammary sinuses for months, and passing out into the milk without causing any disease in the cow.

Variations in Chemical Composition of Milk.

Mr. Charles Crowther, Ph.D., said that while the yearly average composition did not vary at all widely in different years or localities, there was an appreciable seasonal variation from (in tested cases) 3.52 per cent. fat in June to 3.96 in November, and from 8.78 per cent. non-fat solids in August to 9 per cent. in January. The fat content of the morning milk was often much below that of the evening. Causes of variation were the individuality of the cow, advance of lactation (quality improving as lactation advanced), increasing age (producing a very gradual decline in quality), the intervals between milking (the longer the interval the poorer the fat), incompleteness in milking, and the influence of food—a factor commonly exaggerated—on milk secretion. Dr. A. K. Chalmers said that in Scotland a departmental committee was now recommending 3 per cent. fat as the legal standard, but from Dr. Crowther's figures it appeared that in a group of ten cows tested every day for a fortnight the morning milk only once reached 3 per cent. fat, though the evening milk was generally in excess of 4 per cent.

Handling and Pasteurization of Milk.

The most animated discussion of the conference was on pasteurization. It was opened by Professor Georges Dreyer

Oxford, who said that though comparatively low temperatures of 60° C. (140° F.) or rather more for twenty or thirty minutes would avail to kill the bacteria in milk, it was better to have a temperature of 130° to 135° C. (266° to 276° F.) for 3 or 60 seconds. The only effect on the vitamin was likely to be on the antiscorbutic vitamin, but boiling for a short time seemed to be less harmful to this vitamin than exposure to a lower temperature for a longer time, while reheating was fatal to it. Professor Droyer added that pasteurization could not make sanitary precautions on the farm less necessary. He considered that dried milk offered the best solution of the problem of milk distribution in cities. Dr. Charles E. North, of New York, said that at the infant-milk stations in New York, which now numbered 69, about 25,000 babies were fed, in all cases on pasteurized milk, from one source of supply, under a single supervision, the results being checked by doctors and nurses. Since the adoption of pasteurization in New York City the death rate of infants had been reduced from 165 per 1,000 to 70 per 1,000. Dr. Eric Pritchard said that the decrease in this country in infant mortality during the last twenty years corresponded to the increasing use of sterilization methods, though he would not describe that as the only factor. The application of heat was the simplest method of sterilization, and the food value of milk suffered in no degree from being heated. Mr. Nathan Strauss, former president of the New York Department of Health, described the flash-point system of commercial pasteurization as inefficient, since by this process the milk flowing through the chamber continuously was not all subjected to the pasteurizing temperature. To make the milk innocuous it must be retained for twenty-five minutes at 45° to 160° F. Dr. Stenhouse Williams pleaded for more evidence before the value of pasteurized milk was taken for granted—evidence alike as to the extent of epidemic or other disease which was caused by raw milk and as to the possible effect of pasteurized milk in setting up nutritional disorders. Dr. John Robertson (Medical Officer of Health, Birmingham), in a paper on the distribution of milk, said that the distribution of milk in large cities cost as much as milk production on the farm. Moreover, transit involved contamination, which impaired the keeping quality, so that people were deterred from purchasing this important article of food. The ordinary farmer with his existing farm buildings could produce clean milk of good quality if he took some obvious and inexpensive precautions. Two essentials were a steam sterilizer and an adequate supply of cold water. While advocating pasteurization, he criticized the flash-point method, which impaired the antiscorbutic vitamin.

Food Value of Milk and its Care in the Home.

Sir George Newman, who presided over the final session, argued that impaired physique resulted more often from lack of milk than from unsatisfactory milk. The proper care of milk in the home was a matter for education, and instruction ought to be given in this respect to girls in the elementary schools. Dr. Robert Hutchison, in opening the discussion, said that milk was the only animal food which contained representatives of all the nutritive constituents. The casein was a protein of quite special value for repairing waste and building up tissue. Lactose was exceptional among sugars because it was not too sweet and was incapable of fermentation. The mineral salts, calcium and phosphorus, were also of great value. Milk, moreover, was a food with a very high degree of absorbability. From the economic point of view it compared favourably with other animal foods, as a source both of energy and of building material. It had, however, the disadvantage of bulk, and the nutritive constituents were not in the ideal ratio, except for infants. His experience in private practice was that the supply of milk had often to be cut down than to be increased. He found the milk of Jersey cows specially likely to produce bilious trouble on account of its richness. He strongly favoured pasteurization. All the milk at the Great Ormond Street Hospital was pasteurized in the hospital's own plant. In the case of out-patients the mothers were recommended, in the absence of pasteurization, to scald the milk in a double-jacketed saucepan. There need be no fear that pasteurization, by robbing the milk of its proper content, would lead to scurvy. He had never seen a case of infantile scurvy develop as a result of the use either of pasteurized or of dried milk. Dr. Leonard Hill said that overexposure of the milk diminished its vitamins; the mere repeated pouring of milk from one can to another could

have this effect. He would prefer to have milk cheap and dirty rather than to have it pure and dear, but he did not believe that it was necessary to have milk dirty in order to have it cheap. Sir Malcolm Morris also advocated pasteurization, and a speaker from Leicester attributed the decline in infant mortality in that town to the use of dried milk at the infants' milk depôts. In reply to a question, Dr. Hutchison said that intolerance for pasteurized milk on the part of a child must be very exceptional; he had never come across a case in his own experience.

The final discussion, on the education of the public and of the dairy industry, was opened by Sir Daniel Hall, chief scientific adviser of the Ministry of Agriculture.

LIVERPOOL MEDICAL INSTITUTION.

The inaugural meeting of the eighty-fourth session of the Liverpool Medical Institution took place on October 19th, when a large number of members and associates were present to hear the address of the new President, Dr. J. Hill Abram, who spoke on the subject of the medical curriculum. Dr. Abram said that he was attracted to this theme as recently there had appeared no less than three reports on medical education which he had studied closely. These were the Carnegie report, Sir George Newman's report, and Dr. Herringham's report. Dr. Abram said that apparently each lecturer considered that his particular subject required more attention by the medical student than was at present given to it, with the result that if all the teachers were to be satisfied the medical curriculum would have to be lengthened considerably. The number of examinations and their nature were also criticized, and as the student in one university could take one subject at a time, it was pointed out that he might have no less than fourteen ordeals to go through before qualification. He considered that there was at present still a want of correlation between the scientific and clinical subjects, and emphasized the important feature that the practice of medicine, though based on science, was an art. The efficient treatment of the patient was much more valuable in practice than the application of a scientific instrument or the exhibition of a drug. He urged the importance of developing the clinical side of medicine and of making the scientific subjects subsidiary to the main object in view. He suggested that a course of lectures might be instituted with advantage in order to show the true correlation between applied science and the practice of medicine. He held the view that it was of vital importance to free the student during his last three years for the unhindered study of medicine, surgery, and obstetrics. He considered that examinations in the subjects studied during these years should be held only at the end of the fifth year, and that in the first of these years there should be no examinations at all. He thought that the burden of examinations needed lightening, and hoped that in the new changes in the curriculum which were about to be made this point would not be lost sight of. Dr. John E. Gemmell, the past president, proposed, and Dr. R. W. MacKenna seconded, a hearty vote of thanks to the President, which was unanimously carried. Afterwards the President entertained the members to supper, and this was followed by a concert. The endowment fund is now nearly £5,000, and the number of members associated is 435, the largest hitherto recorded in the annals of the institution.

DINNER TO EMERITUS PROFESSOR HENRY BRIGGS.

A large number of friends, former pupils and colleagues, assembled on October 21st at a complimentary dinner to Professor Henry Briggs, who has recently retired from the chair of obstetrics in the University of Liverpool. Major Mark P. Rathbone, president of the Liverpool Maternity Hospital and Ladies' Charity, was in the chair, and proposed the health of Dr. Briggs in terms full of appreciation of the signal services he had rendered to the Maternity Hospital during the long period he had been attached to it. The value of such an institution, he said, had been enhanced by the untiring activity of Dr. Briggs, and he felt it to be a great honour to preside on that memorable occasion. Dr. J. G. Adams, Vice-Chancellor of the University, eulogized the work of Dr. Briggs as professor of obstetrics. He had so developed, or rather created, his department that he ventured to state that it was second to none in the United Kingdom. The obstetric museum, replete with models for teaching and training the student and containing specimens, normal and abnormal, of the various phases of

labour and its complications, was the result of the enthusiasm and personal sacrifices of Dr. Briggs. Indeed, as long as the museum lasted it would be a fitting memorial to his work. Other speakers included Dr. J. Hill Abram, Dr. J. Hayward Willett, Mr. Rushton Parker, and Miss Frances Ivens, all of whom emphasized the enthusiasm and energy which Dr. Briggs brought to bear on everything he undertook. Professor Briggs, in reply to the toast of his health and the appreciation of his work, gave his reminiscences from the time when he became demonstrator of anatomy at the Liverpool Royal Infirmary School of Medicine up to the present. In developing the obstetric department and in using the Maternity Hospital for instructing students and originating an outdoor department for parturient women, he had had many obstacles to surmount and many awkward courtes to turn before success crowned his efforts. As with most innovators success was not always easy and he admitted he often felt like Job. He thanked his friends for the honour they had paid him, assuring them that what he had done for the obstetric department of the University was in itself a work of love and one on which he had concentrated all his energies.

ANNUAL MEDICAL SERVICE AT LIVERPOOL.

The annual medical service took place on October 23rd at St. Luke's Church, Liverpool, when the Right Reverend Bishop Ryle, Dean of Westminster, preached to a large congregation, among whom were the Lord Mayor, the Vice-Chancellor of the University, and the President of the Liverpool Medical Institution. Many medical men were present, some in academic robes, as had been suggested by the Committee. The service was choral and the vicar, the Rev. A. J. M. Macdonald, read the prayers. The Dean took as his text 1 John, 4-7, and emphasized the brotherhood of man. He said that as in science, philanthropy, literature, and art no frontiers were known, so as a result of the great war the principle of the brotherhood of man was being forced on the attention of the reluctant world. He claimed the medical profession to be a constant witness and a glorious interpreter of the fundamental principle of the brotherhood of man. The Bishop of Liverpool read as the lesson the parable of the good Samaritan, and pronounced the blessing. The offertory was taken on behalf of the Royal Medical Benevolent Fund, and amounted to £65 15s. 10d. The honorary treasurer, Dr. J. Ernest Novins, 32, Prince's Avenue, Liverpool, will be grateful if those who were unable to be present would send their donations before the fund is closed.

A LANCASHIRE INSTITUTION FOR MENTAL DEFECTIVES.

From the annual report lately presented by Dr. F. A. Gill, medical superintendent of "Calderstones," a certified institution for mental defectives at Whalley, near Blackburn, Lancashire, we learn that the Lancashire Asylums Board in 1920 allocated the buildings at Whalley, originally erected as an additional county lunatic asylum, for the reception of patients certified under the Mental Deficiency Act, 1913. The buildings were occupied during the war as a military hospital. A working party from Brockhall, a subsidiary establishment, commenced to clear the wards in August, 1921, and there has been a steady influx of defective patients since. During 1921, 391 males and 284 females, making a total of 675, had been admitted; of these 5 had died, 1 had been discharged, and 9 granted licences. There had also been several interchanges between patients at the principal establishment and the subsidiary one at Brockhall. The whole institution has been licensed by the Board of Control for 2,100 defective patients, 1,050 of either sex, and of all grades. The bodily health on reception is described as poor, but 5 deaths only occurred during the year, and influenza was the only epidemic. Dr. Gill is to be congratulated on the progress made in the organization of this large institution, a somewhat complex task considering the varying grades and ages of the patients dealt with. An effort is made to find work of some kind for everyone capable of doing it; 332 males and 268 females are at present employed in work on the land, in the workshops, and in laundry and domestic occupation, while 69 males and 136 females are said to be unemployable. The laundry work is heavier than that of an asylum for the ordinary insane. Dr. Gill does not seem to anticipate much benefit from the school education of mentally deficient children (62 attend the schools), but it may be urged that an appropriate school training by judicious instructors has a value in promoting proficiency of hand and eye as well as of arousing intelligence which is useful in the training necessary to learn a handicraft.

Scotland.

EDINBURGH IN THE SIXTIES.

The inaugural address of the new session of the Royal Medical Society, Edinburgh, was delivered on October 20th, in the rooms of the Society, by Dr. Byrom Bramwell. He spoke on the subject of the Edinburgh medical school and its professors in his student days of 1865-69. He said that when he commenced the study of medicine the Edinburgh medical school was a comparatively small one, the average annual number of medical students at the University during his time being 469, while the average during the past four years was 1,825. The students in those days suffered great disadvantages as compared with the students of to-day as regards both work and play. During the three years when he was captain of the cricket eleven, although they had a fair team, they were very much handicapped because they had no ground to practise on. He did not believe that there was any medical school in the world which had such a remarkable body of men attached to it as the Edinburgh medical school when he became a student. Among them were Sir Robert Christison, professor of forensic medicine for eleven years and of materia medica for thirty-five; James Syme, the greatest operating surgeon of the century; Hughes Bennett, professor of physiology, who was the first to teach the systematic use of the microscope in this country, the first to use cod-liver oil, and gave the knock-out blow to bleeding, which before his time was practised for anything and everything; Lyon Playfair, professor of chemistry, who became a member of parliament and postmaster-general under Mr. Gladstone, and was afterwards made a peer. There were many other men of note, such as Goodsir and Laycock, but the greatest of them all was James Young Simpson, professor of midwifery, who began life as a baker's boy, qualified at 19, and became professor of midwifery at 29; he had the biggest practice that any Edinburgh man ever had, and his funeral was attended by 30,000 people. The men of those days were great personalities, men of very strong will and pugnacious spirit. Dr. Byrom Bramwell trusted that the work of those men would be a stimulus to the members of the society to do what in them lay to maintain and if possible to increase the credit and renown of their great university, their celebrated medical school, and their venerable society.

POST-GRADUATE STUDY IN GLASGOW.

The desire having been expressed for more ample facilities for post-graduate clinical studies during the winter months in Glasgow, the board of the Glasgow Post-Graduate Medical Association has decided to conduct a number of special courses, in addition to the usual weekly demonstrations which have been given in former years. Post-graduate teaching in Glasgow from November to May is, therefore, now available in three forms: (a) weekly demonstrations, (b) special courses, and (c) clinical assistantships. The series of demonstrations will be given on Wednesday evenings and has been arranged much as in former years; the range of subjects is wide, including medicine, surgery, obstetrics, diseases of children, dermatology, ophthalmology, and other special subjects. This series is intended especially to appeal to practitioners who wish to keep in touch with recent advances in a general way, and to compare the methods of diagnosis and treatment employed in different institutions. A feature this year will be the demonstration and discussion of cases sent in by graduates attending the course. The fee for the course is three guineas. A number of special courses have been arranged to meet the needs of those who desire more intensive and systematized post-graduate study, and in these the number of graduates will be limited. These special courses include eight meetings on medical ophthalmology; a course on the study of the welfare of the mother and newborn infant, including lectures and clinical and pathological demonstrations (two courses of nine meetings each have been arranged, one before and one after Christmas); a course on nervous diseases, with special reference to syphilis, conducted at the Western Infirmary; a series of clinical demonstrations on surgical diseases of children, at the Royal Hospital for Sick Children; and a course on clinical psychiatry at Hawick Mental Hospital. The fee for each of the special courses (except that on surgical diseases of children for which no fee is specified) is two guineas. In a certain number of the institutions taking part in the work of the Post-Graduate Medical Association clinical assistantships are available; they

are limited in number and are designed to make provision for graduates who desire opportunities for the detailed study of a special subject; a graduate who desires to obtain a clinical assistantship must enrol for a period of three months, and must be prepared to devote to the work either the whole or part of the day, according to the terms of the particular clinical assistantship which he holds. The syllabus of the courses, containing full particulars, may be had from the Secretary, Glasgow Post-Graduate Medical Association, The University, Glasgow.

GLASGOW MEDICAL LUNCH CLUB.

An interesting meeting of this club was held on October 19th, when the chair was taken by the president, Dr. W. L. Reid, and after lunch Dr. G. C. Cossar shortly addressed the members on his work amongst boys in the poorer quarters of the city. He explained the methods in use for the training of these boys for some definite employment. Particularly he spoke of his boys' training farm within easy reach of Glasgow, and of his farm in Canada to which boys could be drafted. He gave several illustrations of the success attending these efforts in enabling the lads to make good in this country or abroad. Dr. Cossar was followed by Mr. A. Burchard Ashton, Boy Scout Commissioner of Emigration, who spoke more particularly of the very complete organization now in operation all over the world under the Boy Scout movement, whereby following a period of preparation boys could be drafted to the colonies or elsewhere. The thanks of the members were conveyed to the speakers by Dr. McKail.

EDINBURGH HOSPITAL FOR WOMEN AND CHILDREN.

A house-to-house collection is being made in Edinburgh in support of the Edinburgh Hospital and Dispensary for Women and Children and the Hospice in High Street; it is hoped to commence early next spring the erection of the proposed Dr. Elsie Inglis Memorial Hospice in connexion with this hospital. The authorities of the hospital have acquired a site at Spring Gardens, Abbeyhill, and expect that within the next two years the institution will be in full working order. Before progress can be made with the scheme, however, further funds will be required, and the question of endowment must also be considered. It is intended that the new hospice would especially benefit those women who need hospital care during confinement, and who are able to make some contributory payment. The beginnings of the Edinburgh Hospital for Women were made by Dr. Sophia Jex-Blake, who formed a committee and started a hospital of five beds in Grove Street, Edinburgh. From this small institution the hospital at Bruntsfield developed, the new wing of which was opened in 1911 by Queen Mary. The hospital now has 56 beds, including 11 cots for children, and is the first of its kind in Scotland staffed and administered by women. With the work of this hospital the name of Dr. Elsie Inglis will always be associated.

Ireland.

THE WATER SUPPLY OF CORK.

The Resident Medical Officer of the Cork Mental Hospital stated in his last report that the inmates numbered 1,760 (868 males and 952 females). Owing to the reappearance of enteric fever, which has been endemic in this institution for many years, four samples of water from different parts of the house—namely, the kitchen of the infirmary, the general kitchen, the nurses' dining hall, and the superintendent's residence—were sent to University College for bacteriological examination. Professor A. E. Moore reported that inasmuch as the *Bacillus coli* was present in 10 c.c.m. of water in all the samples submitted, the water supply must be regarded as unfit for drinking unless previously boiled. In these circumstances it is thought probable that the cases are attributable to the contaminated water supply. It is hoped that in time it may be possible to prevent or, at least, diminish in number the cases that appear sporadically by the segregation of "typhoid carriers" into special wards, but this would not be of much avail until the quality of the polluted water supply is improved. A member of the Hospital Committee stated that the Corporation had demanded the appointment of a Commission to inquire into the whole system of the city's water supply and also to consider the sewerage question. The report of the resident medical officer showed that the

Corporation's demand was a proper one, and that it was the duty of the Government to appoint the Commission as soon as possible. Though the institution was next door to the waterworks, yet its supply was unfit for human consumption. That is a menace to the health of not only the 2,000 patients in the asylum, but to the 80,000 people of Cork. The Committee directed that the report should be sent to the Waterworks Committee and the Public Health Committee of the Corporation.

VITAL STATISTICS OF THE IRISH FREE STATE.

The Registrar-General in his report for the quarter ended March 31st, 1922, states that there were registered during the quarter in the Irish Free State, comprising 649 registrars' districts, 14,890 births; 7,791 were boys and 7,099 girls, the total being equivalent to an annual rate of 18.8 per 1,000 of the estimated population. This rate is 2.7 below the average for the first quarter of the preceding ten years, and 0.5 below that for the first quarter in 1921. The deaths registered during the quarter, numbering 13,719, of which 6,875 were of males and 6,844 of females, are equivalent to an annual rate of 17.4 per 1,000 of the population, being 1.9 under the average for the first quarter of the preceding decennium, but 1.3 above that for the first quarter of the year 1921. Amongst the causes of deaths the following are mentioned: enteric fever, 24; typhus 3, small pox 0, measles 116, scarlet fever 22, whooping-cough 66, diphtheria 118, dysentery 2, and diarrhoeal diseases 114. Of the 13,719 deaths registered during the quarter 1,166, or 8.5 per cent., were those of infants under 1 year of age, and 6,206, or 45.2 per cent., were of persons aged 65 years and upwards. The number of deaths of infants was equivalent to 78 per 1,000 births registered, as compared with 69 for the fourth quarter of 1921, 79 for the third, and 57 for the second quarter.

Correspondence.

THE DIFFERENTIAL DIAGNOSIS OF SMALL-POX AND CHICKEN-POX.

SIR,—The chief points generally relied on to distinguish varicella from variola and varioloid are the following:

- (a) The distribution of the eruption, which is found most abundantly on the trunk, and more thinly on the face and hands.
- (b) The absence of the eruption from the palms, soles, and palate, especially in young children.
- (c) The absence, or short duration, and unimportant character of the pre-eruptive stage.
- (d) The absence of umbilication of the vesicles in the earlier stages of the eruption.
- (e) The absence of a pre-eruptive rash.

All these distinguishing characteristics, however, may fail, and leave one in perplexity; for in many cases, especially in those in which the eruption is scanty, the distribution on the face and extremities is much the same as that on the trunk. Also sore throat, which is nearly always present in variola, even in the mildest cases, may appear in varicella, accompanied by an outbreak of papules. As to umbilication, in a considerable number of cases of undoubted variola, it is not found at any stage of the eruption; while a slight amount of umbilication may be seen in varicella, when the pock attains a moderate size. Again, in varicella a pre-eruptive stage may occur, which is quite undistinguishable from that of variola.

Other important points which may enable one to decide the diagnosis in favour of varicella are the absence of lumbar pain, the presence of one or more elliptical or oval vesicles, the continued fever after the appearance of the eruption, and the fact that the vesicles collapse on being punctured in one spot only, thus showing that they are unilocular.

There are two signs, however, which are perhaps more reliable than any of these mentioned, and it is to be regretted that more attention has not been drawn to them. They are:

- (a) The early vesiculation and crusting of the papules, which may occur in so short a period as thirty-six hours.
- (b) The contemporaneous presence of papules, vesicles, and crusts on various parts of the body.

This early crusting, invariably seen in varicella and never observed in variola, and the contemporaneous presence of papules, vesicles, and crusts, only found in varicella, ought to have assigned to them the chief place in the list of differential diagnostic signs.—I am, etc.,

Drime'd, E. Yorks, Oct. 22nd.

A. T. BRAND, M.D.

THE HEALTHINESS OF BRITISH HONDURAS.

SIR,—In your issue of July 15th, under "Medical Notes in Parliament," the following statement occurs:

"Dr. Fremantle in his speech instanced the case of British Honduras as illustrating the evil results of the neglect of good advice. Seventeen years ago the late Sir Robert Boyce had, as a result of a visit to British Honduras, described the extraordinary insanitary conditions existing and the prevalence of the stegomyia mosquito, involving the danger of outbreaks of yellow fever. Nothing was done, but outbreaks of yellow fever occurred, the most recent only last year."

It is to be regretted that such an authoritative statement should be incorrect. From the date of Sir Robert Boyce's visit in 1905 no outbreak of yellow fever occurred in British Honduras until 1921.

In 1905 the outbreak occurred in Belize, a town of over 10,000 inhabitants, through which passes all the overseas trade of the colony. It was confined to about twenty cases and was stamped out in six weeks. This was characterized by Dr. J. N. Thomas of New Orleans, one of the leading men of the United States Public Health Service, as one of the finest pieces of work he had seen.

Last year the outbreak took place at a large secondary college about one mile from Belize. Seventeen cases occurred there, but the epidemic was stamped out in sixteen days. Although the epidemic reached the town only three cases occurred there. Surely one might arrive at one of two deductions, either that the "extraordinary insanitary conditions" do not exist, or that the public health service is "extraordinarily" effective.

As a matter of fact, British Honduras is extraordinarily free from infectious diseases. Notwithstanding the fact that plague, yellow fever, small-pox, alastrim, typhus, typhoid, and diphtheria have all been found amongst our nearest and most intimate neighbours, we have managed to keep them all at arm's length with the single exception referred to.

British Honduras is a much-maligned colony, but undeservedly so as regards its health conditions. I have lived here for over twenty-five years, and have only on two brief occasions been off duty on account of ill health, and there are not a few foreigners who can relate the same history.—I am, etc.,

Belize, Sept. 26th.

JAMES CRAN, M.D.,
Acting Principal Medical Officer.

CARDIOLOGY.

SIR,—I feel that your reviewer's comment upon my letter, under the above heading, calls for some response from me; it should make our respective positions clearer. He is in agreement with me that the volume changes in the internal jugular are determined by pressure changes, and I am in agreement with him that the instrument which records the venous waves does not measure the actual attendant pressure values within the vein; but then I did not claim that it did. To do this it would be necessary to occlude the vessel entirely, as in the use of the sphygmograph the artery is occluded.

I think, further, that we shall be in agreement that, *ceteris paribus*, the magnitudes of the venous waves should be directly proportional to the forces (pressures) which develop them. Unfortunately we cannot secure this equality of conditions: and thus whilst, from this point of view, we can more readily compare together the "a" and "v" waves, because they are both determined by pressures operating within the cavities of the heart and are accompanied by volume changes within the vein, as already described, we cannot so compare the "c" wave with either the one or the other. The reason for this is that the "c" wave is generated from without by the impact of the carotid pulse upon the internal jugular, whereby its contents are thrown into oscillation. No question arises here of volume changes due to afflux (the venous flow being held up) or to actual reflux from the heart. The genesis of this wave being so dissimilar it is extremely difficult to see how it and the "a" and "v" waves can be standardized, so to speak.

The issues involved in the problem of the interpretation of the venous pulsations are, I think, much more complex than has been generally accepted, and for this reason I have elsewhere ventured to suggest that the whole subject, including the nomenclature of the waves, should be reconsidered.—I am, etc.,

London, Oct. 23rd.

HARRINGTON SAINSBURY.

PSYCHO-ANALYSIS.

SIR,—Having been during all my professional life much interested in all neurological and psychological questions, I have dipped frequently, like Dr. McBride, into the literature of this subject, and must confess that to me it has an unsatisfying character.

I do not specially refer to the nauseating aspect which would give sex such a prominent part, and indeed probably the most prominent part, in the thoughts and conduct of most of us, but I refer at present more especially to what Sir Clifford Allbutt mentioned in his recent lecture. Some of the writers and practisers of psycho-analytical methods use too seldom the ordinary language of the physical, anatomical, and physiological sciences, and use much more freely indefinite and abstract language of metaphysics, with the result that it is difficult to get a clear concrete idea of what exactly they mean.

It seems to me that there are facts that if not altogether forgotten by some of them are not sufficiently emphasized. I refer to such facts as that the brain is the organ of mind, that the mind only shows itself by the action of the brain, that the brain is an organ having a physical and anatomical construction capable in health of physiological activities, and when diseased of activities depending on the pathological modifications of its physical and anatomical construction and usual physiological activities.

We have such terms as repression, idea complexes, censors, instincts, wishes, conscious, subconscious, etc., introduced without it being sufficiently borne in mind that the processes or activities of the brain on which these depend have a physical basis. It has always appeared to me that unless one has an idea of the physical, anatomical, and physiological basis underlying these terms much of the discussions of the subject, I will not say is jargon, but words—words!

I do not in the least wish to detract from the good work which can be accomplished by psycho-analysis in the way of treatment because I know how successful it has been in many cases and especially since the war, what a scope there is for such work, and in spite of their methods how great the number of poor souls there are still waiting for an even more successful method of cure than psycho-analysis has proved to be.

Perhaps some of the successful cures have been too readily attributed to the fact that after much probing into the subconscious the practitioner has managed to fish up something which he considers was the initial cause of the disorder which he set out to treat. One must, however, recognize that there is hardly any form of treatment which is so capable of "suggesting" to a patient that he is likely to be benefited by it as psycho-analysis. The long sediments at intervals, the questionings, the proings, and at last the discoveries by the practitioner of what the patient himself even had forgotten, are all calculated to produce an atmosphere of "suggestion" that all will be benefited. And he benefits accordingly. Whilst many of the cures may thus be brought about by suggestion, I do not by any means imply that all are, and if the psychoanalysts would emphasize more the physical, anatomical, and physiological basis subserving their methods they would, I think, not only place their practice on a more certain scientific basis but establish more securely some of the truths underlying their methods.

It is not possible, of course, with our present knowledge to understand many mental phenomena which in the gradual advance of science may probably fully be accounted for by the physical and anatomical construction and the physiological and pathological activities, past and present, of the human brain. Probably it is not possible fully to account for such processes at present as repression, coming into consciousness, complexes, etc., from the physical side, but I believe a working hypothesis could be developed on the lines of what has been done by investigators on the disorders of speech, memory, etc. These, of course, are of a simpler and more localized kind than many of the neuroses, neuro-psychoses, and psychoses with which the psychoanalysts have been concerned.

In the paper by Dr. Crichton Millar, read at the Glasgow meeting, I was glad to see psychology considered in one direction on the lines of what I mean when he showed some of the effects the internal secretions of the endocrine glands or their absence may have in activating or biochemically acting on special organs or on specialized cells of the body and brain. Such localized or special action on picked out cells, or groups of cells, may profoundly alter the nature and

conduct of an individual. Although we may not know the why and wherefore of the action of those glands, the terms used to describe the process are fairly understood, because they are those of physics, chemistry, anatomy, and physiology.—I am, etc.,

Leith, Oct. 22nd. WILLIAM ELDER, M.D., R.C.P.E.

SIR,—It is a matter for regret to find from Dr. McBride's letter in your issue of October 14th (p. 704) that he did not obtain the information he expected from the replies to his previous letter on August 12th.

Really, the subject to be thoroughly understood requires discussion and the test of practice, which is best undertaken at one of the teaching clinics. If Dr. McBride has the leisure to follow this course he will find the subject of psycho-analysis and the psychological basis on which it rests cleared of the difficulties which now present themselves. He will also learn that this method of treatment is not claimed to be a perfect therapeutic weapon, and that, in its present form, it has its limitations. Even so a greater measure of success has attended its use than can be claimed for any other method of treatment.

Dr. McBride refers to Sir Clifford Allbutt's address at St. George's, which he hopes will call for a defensive reply. I hope it will. It has been stated that the time required and the expense militate against the practice of psycho-analysis. I think Dr. McBride will agree there are many diseases in the domain of medicine in which the treatment is both protracted and expensive. Just now there is a wave of criticism adverse to psycho-analysis and its foundation which will do good by ventilating certain aspects of these subjects.

The majority will agree with Sir Clifford Allbutt that the mental investigation of children by their teachers may be most harmful, and the admission of crime as a pathological condition would tend to defeat the ends of justice. Rather let the teacher be trained to detect abnormalities in the child so that suitable skilled treatment may be undertaken sufficiently early—which, in itself, would eliminate pathological crime to a large extent—and leave the criminals in the hands of his judges, who always exercise their prerogative in favour of the accused where circumstances allow.

Sir Clifford's reference to the mind as a pint pot brings forth the obvious reply that we are not concerned with the quantity of the psychic content but with its quality—it may be a dangerous mixture liable to explode.—I am, etc.,

Ministry of Pensions Hospital, JAMES W. W. ADAMSON, M.D.
Hednesford, Staffs, Oct. 18th.

SIR,—When psycho-analysts discuss the subject with sceptics, there always seems to be a certain vagueness, and also a more or less implied suggestion of want of understanding on the part of their opponents. This tendency seems to be present in Dr. Steen's letter, although, as one would expect, it is veiled by exquisite courtesy.

However, he has chosen certain works as guides, so in order to keep this letter within reasonable dimensions let us consider the views of Freud upon dreams. This is all the more fitting as that author himself has written (*Interpretation of Dreams*, p. 483): "At any rate, the interpretation of dreams is the *via regia* to a knowledge of the unconscious." Now, as the unconscious seems thus to be the foundation upon which psycho-analysis is built, it is fair to assume that if this foundation be shaky the whole structure is in danger of falling. It is unnecessary to remind Dr. Steen that Freud's views as to "dreams, wit, folklore, ethnology, myths, aesthetics, the science of religion," and, he might have added, symbols, rest upon the theory of an unconscious mind which acts as a storehouse for—shall we say?—suppressed knowledge.

This being so, the first question an intelligent student of the work will ask is, "How am I to reconcile this theory with known physiology?" Probably he visualizes ordinary thought as a change in certain brain cells due to some stimulus—visual, auditory, or sensory. He assumes the action of nerves and nerve cells, followed by rest and recuperation, but how is he to explain to himself the unconscious mind in the Freudian sense? As the difficulty can thus be stated in comparatively few words, perhaps Dr. Steen will either be able to remove it in like manner or by mentioning Jung's recent book on the unconscious, but have again only found assumption where I had hoped for reasoning.

Another question arises. Apparently this storehouse of unconscious thought has within it a hidden knowledge of

symbology which the interpreter freely utilizes in explaining dreams. How does he know that what he elicits from the patient, and assumes to come from the unconscious, is not suggested to him in some way, and why does he assume that it has had anything to do with his dreams?

It would take up too much of your valuable space to consider Freud's views on this, but I may be permitted to state that so far as I can gather the following points are insisted upon by that author:

1. The dream is not what it seems to be.
2. One person may represent another or several persons.
3. Something which appears quite unimportant is really the most important thing.
4. A thing may stand for its opposite.
5. We have to be guided by the symbols to which reference has been made.

It may be mentioned that these symbols are generally supposed to be sexual—most long objects represent the male organ, most short ones the female genitalia, and "rhythmic" motions, such as climbing and riding, coitus.

I may conclude by a quotation:

"We have already asserted elsewhere that dreams which are conspicuously innocent invariably embody coarse erotic wishes, and we might confirm this by means of numerous fresh samples" (p. 241, Freud, op. cit.).

From what we have thus gleaned from the work which Dr. Steen specially recommends for study to the budding psycho-analyst it would not be unjust to infer that a dream may be made to mean almost anything. Fortunately, most readers of this discussion will have had many dreams, and so this aspect at least may be left to the decision of those who incline to attune their beliefs to the dictates of common-sense.

I feel that I have already occupied too much space and shall content myself by congratulating Mr. Arthur Lynch on his very pertinent criticism, which, coming from an author of his well-known attainments, proves that psycho-analysis does not always appeal to intelligent minds. With regard to Mr. Bryan's strictures: the onus of proof that there is any difference between psycho-analysis and the confessional rests with him and those who share his views. Why should disciples of Freud refuse priests access to that very dubious thing which they call "the unconscious mind"?—I am, etc.,

Harrogate, Oct. 22nd.

P. McBRIDE.

BACTERIOLOGY AND THE VACCINE TREATMENT OF CHRONIC BRONCHITIS.

SIR,—Dr. Leonard Mackey in his helpful article on the "Bacteriology and vaccine treatment of chronic bronchitis" in your issue of October 21st (p. 715) has suggested that rhinologists could throw light on the real nature of the associated nasal infections, and suggest some useful local treatment.

Dr. E. Rist, as reported in the same issue, draws attention to the connexion between chronic infection of the upper air passages and chronic cough and symptoms simulating incipient tuberculosis. I would go further and submit that, quite apart from infected air sinuses, enlarged turbinates, adenoids, etc., chronic naso-pharyngeal catarrh sets up, in certain people, a condition that lowers their vitality and makes them more susceptible to succumb to tuberculous and other infections. Among such sufferers can be included many medical practitioners, especially those in industrial districts. Various nasal operations, autogenous vaccines, nasal douches and sprays may be tried in vain, and the condition persist, bringing in its train troubles such as rheumatoid arthritis and the like.

Much work, I know, has been done in connexion with the naso-pharyngeal flora, but it seems that very little progress has been made in the local treatment of this condition. What would be much appreciated is a communication on the subject by some eminent rhinologist, giving the various forms of treatment and the degree of success that can be looked for in each.—I am, etc.,

Edinburgh, Oct. 23rd.

W. GOLOIE.

UNSUSPECTED PREGNANCY.

SIR,—Would Dr. Graham Grant consider the following case one of unsuspected pregnancy?

On February 23rd, 1921, I was called by telegram to a woman five miles away; it was the usual "come at once" message, and I went. I was somewhat disgusted, therefore, to find on arrival that the patient—a woman—was sitting by the kitchen fire looking far from ill. I inquired the reason for the telegram, and was

informed by her that she had a "cold." When she stood up I saw at once that she was about full term in pregnancy. Her symptoms of a "cold" were pains in the back and abdomen; and when I remarked that I thought it was probably the commencement of labour she was most indignant and said, "That's what my husband says, and it's nothing of the sort." Her husband and her aunt had both incurred grave displeasure by making the correct diagnosis some time previously, but the patient had refused to allow any such possibility, and would get quite angry at the idea. There was no guess on as to the genuineness of her belief that she could not be pregnant, for she had made no arrangements—no baby clothes, and had no other bedroom nor bedclothes prepared.

I examined her and found labour well started, and I told her that it was a fortunate thing that everybody who had a "cold" had not her symptoms. Six hours later the child—rather on the large size—was born. Just when the head was crowning her aunt came up to say that the nurse was wanted elsewhere. I told the nurse that she could not possibly go till the case was over, whereupon the patient half raised herself in the bed and looked over her shoulder and remarked, "Can I be of any assistance?"

This patient was living with her husband, had been married about a year, and could not by any chance be said to be dull-witted. She is a tall woman, and her menses had ceased in the ordinary way. I said to her that I could not understand how she did not know that she was going to have a baby, that she must have known that a young married woman would naturally expect such a possibility, especially when her abdomen began to get large. To this she replied, "Well, I was brought up by a step-mother, and I don't think that she took quite such an interest in me that my own mother would have done."

I am afraid that Dr. Graham Grant will think I am pulling his leg, but this is not an American tall story—just the literal truth of what actually happened. The unfortunate woman was unmercifully chaffed by her neighbours, for of course the story became "broadcasted," as such happenings do in the country.

The interesting thing will be to see how "the child imposes on the man"; this child cannot be affected by any of the usual fears and introspections which occur in the average expectant mother.—I am, etc.,

Newick, Oct. 20th.

J. CHANSLEY MACKWOOD.

SIR,—May I contribute an experience of a few years ago?

In response to a telephone message announcing an unexpected birth I reached the patient about 7 a.m. and found that she had delivered herself half an hour previously, not only of a full-term living child, but of the placenta. Absolutely nothing had been done for mother or child before I arrived. The one and only pain had occurred a few minutes before the birth, when, wakened by it, she roused her sister to prepare some hot milk to relieve what she called cramps in the inside. When the sister returned with the milk the child was born and I was sent for. She assured me that she had never suspected pregnancy. Neither had her sister, who had shared her bed for months previously, nor any of the other members of the household. The menses had been regular, and there were no peculiar or abdominal developments noticeable. This is the truth, but, alas! not the whole truth. My patient was unmarried—a much-appreciated servant in a respectable family, and the startling surprise of that morning filled them with disappointment and mortification.

When I mentioned this case to some of my colleagues they listened courteously, suffered me patiently, but pitied my credulity. The girl's mistress was Christian enough not only not to cast a stone at her sister-woman but to take her back to service in the course of a few weeks.

The question is, Should we discredit a tale of unsuspected pregnancy except in those cases where the woman prudently shrinks from the burden of maternity unless she has the moral support that is afforded by the wedding ring?—I am, etc.,

Belfast, Oct. 14th.

WILLIAM L. STORRY.

SIR,—I remember telling a patient of mine a story of my dog, considered by me a remarkable animal, and the lady replied: "Oh, that is nothing! Our dog, being too big to get into a mouse hole, fetches the trap and, having soon that the cheese is all right, places it carefully just where the mouse must see it and sits himself down to wait." I said, "Thank you very much for the lesson. Good-day."

I feel I have to repeat this contrito observation to Dr. Lewis in view of his "true tale" of the twins (it will be triplets next week, I expect; then Heaven help me!), because I do not desire to get myself further disliked by advancing suggestions which might give offence. It is abundantly clear that I have failed to profit by my experience of nearly 3,000 cases, and I must therefore admit that the words "Verbum sapit" do not apply to me. If the Editor of this Journal

wishes them to apply to him he will be well advised to close this correspondence before we have to deal with a quadripara.—I am, etc.,

London, W., Oct. 20th.

GRAHAM GRANT.

We are disposed to accept Dr. Graham Grant's advice, but not for the reason he gives.

DAINGEROUS DRUGS ACT, 1920.

SIR,—It is well known that in the past the sending of missionaries to unexplored regions has been encouraged; and large sums of money contributed for the purpose by men whose object was not the improvement of the heathen, but the acquisition from them of ill-gotten wealth. Similarly traders of an unscrupulous character are continually making "cat's-paws" of well-intentioned people to enable them to oust competitors and increase their own profits from trade of a pernicious kind. Some years ago there was vigorous agitation in favour of measures to put a stop to objectionable traffic in opium. I am quite convinced that this was largely fostered in the interests of an unscrupulous section of the persons engaged in that objectionable traffic, or interested in it. Now we have good people supporting legislation to suppress improper traffic in the so-called "dangerous drugs" (cocaine, etc.). I have little doubt that the same sort of influences are working secretly behind them, and behind the newspapers which have given so much of their space to the subject. The result, if I am any judge, is an increase in the misuse of cocaine, through the unprecedented advertisement given to the drug, and very large profits to traders of the worst types; and, at the same time, loss and inconvenience to honest and reputable traders and doctors. In conclusion, let me ask whence the General Medical Council derives its authority to give, or withhold, its "concurrence" with orders such as those recently issued by the Home Office?—I am, etc.,

Oakhurst, Lingfield, Oct. 20th.

HUGH WOODS, M.D.

DERMATITIS AMONGST CEMENT WORKERS.

SIR,—Recently I was called to see a man who was suffering from a generalized dry scaly eczema. The scales were abnormally large, some measuring 1 cm. square, and easily detachable. When removed a red, glistening, but dry surface was left. The disease started on the outer aspect of the right leg, just above the malleolus, and, when I first saw him, extended all over both legs and thighs. The upper limbs were both affected from the shoulders to the wrist, and painful fissures were present in the flexures of both upper and lower limbs. The back and chest were almost entirely covered, the head and neck comparatively free. Desquamation occurred rapidly, and when a hand was passed across the back a shower of scales fell off like chaff into the bed. The finger-nails were uneven and fissured. The condition yielded to treatment by liquor carbonis detergens and liquor plumbi fortis followed by olive oilunction.

The patient was a foreman rough-caster and attributed his condition to working with cement, informing me that another workman—whom, however, I did not see—had the same complaint in a minor degree.

I have failed to find in any of the works and reports I have consulted any reference to cement as a cause of occupational dermatitis, and should be interested to hear if this has been described.—I am, etc.,

Glasgow, Oct. 16th.

S. NORMAN DYKES, M.B., Ch.B.

THE RADICAL PREVENTION OF VENEREAL DISEASE.

SIR,—Please permit me to explain to your correspondent, who blames my letter in your issue of October 7th for its insipidity, just how that came about.

Time was when I could be guilty of a spicy, stinging letter. The same might be said of Mr. Lloyd George. It applies with equal truth to my friend Mr. Bottomley. But I have been more fortunate than they. You, Sir, have taught me wisdom. Some six months ago I sent you a spicy, stinging letter on the same subject—the prevention of venereal disease. You courteously advised "postponement" of its publication. Time, aided by Gilbert and Sullivan, completed the lesson for me. I bow—humbly and gratefully—to your superior wisdom. Who should know better than the Editor of the BRITISH MEDICAL JOURNAL that spicy, stinging

sentences do not greatly advance the public good? Hence the comparative tameness of my later letter which you did publish.

Let us hope that Mr. Lloyd George—and Mr. Bottomley—will in time be equally fortunate. But of course allowances will have to be made for them. They have not the advantage—as I have had—of the kindly guidance of an experienced medical editor, free, gratis, and for nothing! Prossuro of work doubtless must excuse Mr. Lloyd George if through neglect of his duty to Gilbert and Sullivan he has as yet not learnt that it is “*calm deliberation*” that “*disentangles every knot*.” A stinging style creates a stormy atmosphere which makes calm deliberation impossible, whether in medical journals or elsewhere.

This, however, is digressing. My letter was never intended, as your correspondent hints, to discredit the fact, the beautiful fact, that disinfectants do disinfect. Am we for that reason to shut our eyes to the fact, the ugly fact, that calomel cream can never cleanse the dirty mind of a single sensual sinner? Your correspondent's other assertions must be left to others who are better able to deal with them.

Your correspondent “G.”'s criticism (October 14th, p. 706) is suggestive and very much to the point. He inquires whether I realize all that “a universally applied habit of unselfish thinking, practised every day in every way” would lead to. He sees that it would involve the reconstruction of society. Most certainly neither I nor anyone else realizes all that it would lead to. For example, how many see that it would also lead to as great a renaissance of science, art, and literature as the world has ever witnessed? For in those things the best and finest work is never inspired by a selfish motive. To what do we owe our knowledge of the fact that disinfectants do disinfect? Is it not the outcome of many an hour of patient, unselfish thinking done for our benefit by Lister and Pasteur?—I am, etc.,

Sheffield, Oct. 23rd.

HERBERT CAIGER.

Sir,—During and just after the war I lectured on venereal diseases to about 500,000 of our troops, including a fair number of colonial and overseas soldiers, both as units and in cadet training schools. Whenever I spoke to them I always appealed to their patriotism and put it up to them how much better they would be employed pumping lead into the Hun rather than lying in hospital and having “606” pumped into them. Practically on every occasion those words were greeted with acclamation and enthusiasm. I wish to protest most strongly against the imputation conveyed in Miss Ettie Rout's letter in your last issue (p. 777) that numbers of men deliberately allowed themselves to be infected with this disease to escape the firing line. I am not denying that among all the millions of men under arms there may have been an infinitesimal number who took this course in an attempt to save their skins; but from my experience, based on an enormous number of talks outside lectures with soldiers from all parts of the empire, I am absolutely certain that this particular cause of infection was practically negligible. I write this letter because I am very jealous of the fair fame of our soldiers.—I am, etc.,

London, Oct. 23rd.

E. B. TURNER.

ANIMAL EXPERIMENTS.

Sir,—You have published a letter from Dr. W. W. Keen, of Philadelphia, U.S.A., which directly challenges the “consistency” of our President, Dr. Hadwen, who is in America. I trust that you will not allow this challenge, obviously based on error, to remain uncorrected. Dr. Keen asserts that Dr. Hadwen “advocates” the law under which experiments on animals are performed in this country. That is false. He also states that Dr. Hadwen gives “unconscious advocacy” to the use of antiseptics by his supposed approval of the law. Dr. Hadwen does not advocate antiseptics, consciously or unconsciously. Like most advanced surgeons, he believes in *asepsis*, of which Lawson Tait, Granville Bantock, and Sir William Savory were pioneers, practising it in defiance of antiseptics, then fashionable.

Errors similar to Dr. Keen's are bound to be made by anybody who hastily concludes that “Mr. Coleridge and Dr. Hadwen” advocate the same things. Mr. Coleridge—who is the director of a society one-third the size of that to which Dr. Hadwen devotes purely voluntary service—“directs” his society by a policy totally opposed to ours.

I take the opportunity of Dr. Hadwen's absence to state their relative positions, which ought to be known within the medical profession, although much misunderstood without.—I am, etc.,

B. E. KIDD,

Secretary, British Union for Abolition of Vivisection.

London, S.W., Oct. 23rd.

POST-GRADUATE COURSES.

Sir,—I was glad to read your article on post-graduate courses (October 7th, p. 650). Any scheme which adds to the facilities for obtaining such instruction will, I am convinced, be of very great interest to a great number of us. But there are many of us who, having gone into practice in the near provinces, view with horror our gradual separation from the scientific, our gradual deterioration, fancied or real, into the “cold on the liver,” “sick headache” type of diagnostician. Yet it is difficult for many of us to prevent this.

We are hard up, we have to work to keep our local tradesmen prosperous. We come home too tired or too slack to read. We cannot afford to spend a week or a fortnight away from our work. In other words, it is very difficult for us provincials to avail ourselves of the existing facilities, and we have none here. Our local hospitals are closed corporations, and do not teach. For the life of me I cannot see why. We have clinical meetings from time to time and enjoy them, but they do not follow the lines of a post-graduate course, and some of us, tied up in the afternoon, cannot attend even these.

I am certain something ought to be done for us, and my suggestions are as follows:

1. That every local general hospital be made a centre for post-graduate courses. Lectures and demonstrations to be given once a week in the evenings, the most suitable time being 5 to 6. Or
2. That post graduate classes be held once a fortnight in London on some special subject, necessarily in the evening, say from 6 to 7, or, if this is not feasible, in the afternoons.
3. That these courses be free, or as nearly free as possible.

The advantages to be accrued are obvious; I should be glad to hear the opinions of other “provincials.”—I am, etc.,

October 14th.

“AMBITIOUS.”

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

THE following candidates have satisfied the examiners in both parts of the Examination indicated:

D.P.H.—Marjorie Back, Muriel Brown, J. G. Campbell, J. Davidson, J. Forsyth, A. W. Gaby, Beryl Grierson, J. G. F. Hosken, E. S. Macphie, D. R. Mehta, D. E. Morley, Edith M. Neilson, Sybil M. Nuttall, G. P. N. Richardson, T. E. Roberts, H. A. Ross, G. M. Sanderson, H. E. Seider, W. A. Warden, J. Young.

† Distinguished in the application of Sanitary Science.

Diploma in Hygiene.

The first examination for the Diploma in Hygiene, recently established by the University for foreign medical graduates, was held this month. The following candidate satisfied the examiners in both parts of the examination (with distinction in the principles of hygiene): Chung Hsin Han.

UNIVERSITY OF LONDON.

A course of eight lectures on the “Histology of the nervous system” will be given by Dr. C. Da Fano at King's College (Strand) on Wednesdays, October 25th, November 1st, 8th, 15th, 22nd, and 29th, December 6th and 13th, at 4.30 p.m. Attendance at this course is recognized in connexion with the B.Sc. (Honours) degree in Physiology. Admission is free without ticket.

SCHOOL OF HYGIENE.

At a meeting of the Senate held on Wednesday, October 18th, the Vice-Chancellor (Mr. H. J. Waring, M.S., F.R.C.S.) being in the chair, a communication was received from the Minister of Health forwarding draft heads of agreement with reference to the School of Hygiene which is to be established as a school of the University under the donation of two million dollars made for the purpose by the Rockefeller Foundation. The agreement provides for the erection of suitable buildings on a site in Bloomsbury and the constitution of a board of management and a court of governors for the control and administration of the school. Resolutions were adopted expressing the concurrence of the University in the proposed scheme and the very great satisfaction with which the Senate learnt of the munificent contribution of the Rockefeller Foundation and of the intentions of H.M. Government with regard to the maintenance of the school.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

AN extraordinary Comitia of the Royal College of Physicians of London was held on Thursday, October 19th, at 5 p.m., the President, Sir Humphry Rolleston, being in the chair.

The modification of By-law CLXXXVIII, passed for the first time at the last Comitia, was now passed for the second time. In consequence of this the by-law now reads as follows:

"No Fellow of the College shall be engaged in trade, or dispense medicines, or make any engagement with a pharmacist or any other person for the supply of medicines, or practise medicine or surgery in partnership, by deed or otherwise; or be a party to the transfer of patients or of the goodwill of a practice to or from himself for a pecuniary consideration."

The former text of this by-law was:

"No Fellow or Member of the College shall be engaged in trade or dispense medicines, or make any engagement with a chemist for the supply of medicines, or practise medicine or surgery in partnership, by deed or otherwise; or be a party to the transfer of patients or of the goodwill of a practice to or from himself for a pecuniary consideration."

(Words omitted or altered are printed in italics.)

The following resolution was passed for the first time:

"That By-law CXIV, which relates to candidates for the Membership, be repealed."

This by-law reads as follows:

"No candidate shall be admitted to examination who is engaged in trade; or who dispenses medicine, or makes any engagement with a chemist for the supply of medicines; or who practises medicine or surgery in partnership, so long as that partnership continues."

The following resolution was passed:

"That subject to the provisions of By-law CXC it is undesirable that any Fellow or Member of the College shall have any financial interest (whether direct or indirect) in any company or institution having for its object the treatment of disease for profit, other than the receipt by him from such company or institution of (1) a fixed salary, or (2) fees, for such services as he may render to such company or institution in his capacity of medical practitioner."

This is intended to replace the resolution passed by the College on October 25th, 1888—namely:

"That it is undesirable that any Fellow or Member of the College should be officially connected with any company having for its object the treatment of disease for profit."

The President then dissolved the Comitia.

UNIVERSITY OF EDINBURGH.

At the graduation ceremony on October 21st the following medical degrees and diplomas were conferred:

M.B., Ch.B.—J. W. Anderson, F. Booth.
D.P.H.—Jenn Murray.

UNIVERSITY OF ABERDEEN.

The Alexander Anderson Scholarship in Medicine, tenable for two years, has been awarded to Robert Craikshank, M.B., Ch.B.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Calendar for 1922-23.

THE Calendar of the Royal College of Surgeons of England for the current year has lately been published, and contains the usual information arranged upon the customary plan. The report of proceedings of Council shows that 52 diplomas of Fellowship (including 3 to women) were issued during 1921-22, and 334 diplomas of Membership (including 91 to women). The Diploma of Fellowship by examination (with ophthalmology) was granted for the first time. The licence in Dental Surgery was issued to 194 persons (including 4 women), and the following are the numbers of diplomas granted jointly with the Royal College of Physicians: Public Health, 69; Tropical Medicine and Hygiene, 58; Ophthalmic Medicine and Surgery, 25; Psychological Medicine, 24. Mr. Charles Brook, of Lincoln, and Mr. William Coxes, of Manchester (members of twenty years' standing), were admitted to the Fellowship without examination. The subject of the Jacksonian Prize Essay for the year 1923 is "The pathology and treatment of malignant disease of the testicle."

Reference is made in the report to the fact that the annual meeting of Fellows and Members summoned last year did not take place as the required quorum was not obtained. A report is presented on the irregular meeting held on that occasion after the President's withdrawal, and attention is called to Section XVII of the By-laws under which those holding an unauthorized meeting render themselves liable to suspension from privileges or removal from being a Fellow or Member.

The financial report states that the income of the College, exclusive of that from trust funds, amounted to £39,815, or £1,852 more than the previous year, and that the total expenditure in

previous year. The balance of the revenue account amounted to £5,563. The valuation of investments at June 24th last showed a considerable improvement. The Conservator's report has already been noticed, but we may recall that under the agreed terms of trust the Council of the College becomes responsible for the housing display, completion, upkeep, and cataloguing of the Army Medical War Collection, spoken of in previous reports under the title of "War Office Collection." The collection thus added forms an intrinsic part of the College museum, but the contents are at the disposal, for teaching purposes, of professors at the Royal Army Medical College, Millbank. When complete, it is estimated that the Army Medical War Collection will comprise 2,000 wet specimens and 500 dry specimens, besides drawings, radiograms, photographs, models, and casts. Before the end of the present year it is hoped to furnish the new quarters with cases, stands, and begin the installation of the collection in the new accommodation under construction. During the present year Lieut.-Colonel R. H. Elliott has made an addition of great value to the Museum by his collection of eyes showing the lesions which may result from the operation employed by native practitioners in the treatment of cataract. The report on the library states that the *Lives of Fellows* compiled or written by the librarian, Mr. Victor G. Plarr, amount now to 2,453; they are being fully indexed. The period covered is from 1843 to the present time.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.

At the meeting of the Royal College of Surgeons of Edinburgh, held on October 18th, Sir David Wallace, C.B.G., was re-elected President for the ensuing year; Dr. George Mackay, Vice-President; and Mr. Alexander Miles, Secretary and Treasurer.

The following 19 successful candidates out of 62 entered, having passed the requisite examinations, have been admitted Fellows:

P. M. Brodie, W. A. Brown, D. Buchanan, J. T. Carson, J. S. M. Connell, J. Dancel, E. L. Ferguson, H. L. H. Greer, C. R. R. Huttable, Marjorie M. Jefferson, I. H. Jose, L. C. E. Linton, G. A. Petrie, E. H. Radon, B. S. Simpson, H. V. Tink, V. N. Whitmore, J. L. Wilt, Ethel D. Wilt.

Dr. Kandappa Rajah, having passed the requisite examination, has been admitted a Licentiate of the Royal College of Surgeons of Edinburgh.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

At the Annual Stated Meeting of the President and Fellows, held on St. Luke's Day, October 18th, the following Members of the College were elected Fellows: Leonard Abrahamson, M.D. Univ. Dubl.; Joseph Warwick Bigger, M.D. Univ. Dubl.; Charles Dickson, M.B., R.U.I., M.D. Queen's Univ. Belfast.

The following officers for the coming year were elected:—President: Michael Francis Cox, Hon. M.D., R.U.I. Censors: Sir William J. Thompson, M.D. Univ. Dubl.; William Joseph Dargan, M.D., R.U.I.; John St. Tottenham, M.D. Univ. Dubl.

The Comm. Scheme: Edward J. Gwynn, M.D., R.U.I., Fellow of Trinity College, Dublin. Council: Sir J. D. Registrar: t. G. J. Phelps. to act as Vice-

President of the College. Additional examiners to take the place of an absent censor or examiner, examiners for the licence in midwifery, supplemental examiners under the conjoint scheme with the Royal College of Surgeons in Ireland, examiners for the Certificate in Public Health, examiners for the

various collegiate (showing examiners Languages: E. H. mathematics; Regi- of Trinity College, Dublin. In Irish:

Edward J. Gwynn, Fellow of Trinity College, Dublin. The annual report of the library committee, recommending the publication of correspondence between Archbishop and Sir Patrick Dnn, first and Queen's College of Physicians in Ireland,

THE Denver city council (Colorado, U.S.A.) has set aside 20,000 dollars as a contribution from the city to the University of Colorado Medical School and Hospital, the establishment of which was made possible by donations from the Rockefeller and Carnegie Foundations.

A SANITARY conference of the South American Republics will be held in Montevideo in January, 1923. Among the subjects to be discussed will be the medical curriculum, and the best means of furthering scientific interchange in South America.

By the will of Dr. W. S. Halsted (of whom an obituary notice appeared in our issue of October 7th, p. 663), the residue of his estate, valued approximately at 100,000 dollars, is left to the Johns Hopkins University, subject to the payment annually to his widow of 5 per cent. of the value of the legacy. The bequest is to be devoted to research in medicine, preferably in surgery, and is not to be used for buildings.

Obituary.

SIR JAMES GALLOWAY, K.B.E., C.B., M.A., M.D.,
F.R.C.P., F.R.C.S.

Consulting Physician to Charing Cross Hospital.

THE death after a short illness, due to the complications of renal calculus, of Sir James Galloway during his full tide of activity removes from the scene of medical life in London a figure prominent in many directions.

Coming of an Aberdonian stock, he was born at Calcutta in October, 1862, and on account of the age limit had resigned his post as senior physician to Charing Cross Hospital as recently as October 13th last. He received his early education at the Chaucery School, Aberdeen, and then proceeded to the university, where he took the degrees of M.A. (1883), M.B., C.M. (1886), and M.D. with highest honours (1892). His university gave him the honorary degree of LL.D. in 1919; he had taken the F.R.C.S. Eng. in 1889, and about this time

had started work at the London Hospital, where he came under the influence of the late Sir Stephen Mackenzie, by whom he was imbued with the importance of dermatology as an aspect of general medicine—a subject on which subsequently he often wrote. For a time he was demonstrator of materia medica in the medical school of the London Hospital, but he was much more interested in pathology, and was soon appointed pathologist and assistant physician to the Great Northern Hospital. His industry, especially in the microscopic investigation of malignant disease, was early recognized by his appointment to give the Morton lecture on cancer at the Royal College of Surgeons in 1893; the lecturer in 1892 was the late Sir German Sims Woodhead, who preceded him into the valley of the shadow a little more than nine months ago. Galloway's Morton lecture on the "Parasitism of protozoa in carcinoma," reviewed the position of the subject, much debated at that time by Ruffer, Plimmer, and J. Jackson Clarke at the old Pathological Society of London, but with the wise caution that always characterized his judgement he left

their causal relation an open question. That his outlook in pathology was wide is shown by a well-illustrated paper on syringomyelia read before the Pathological Society in 1891, and by another in 1894 on the bacteriological diagnosis of membranous inflammation of the throat based on eighty personal observations. In this year his long connexion with Charing Cross Hospital began by his appointment as physician to the skin department, where he worked until 1914, having in the interval passed up the rungs of the ladder as assistant physician (1901), full physician (1906), and senior physician (1913); in the medical school he filled various offices, the last being lecturer on medicine (1908–22). As examiner in medicine at the Conjoint Board, at the University of London, and for the Medical Service of the Royal Navy as a member of the Advisory Board for Army Medical Services his eminence as a general physician was justly recognized. Further evidence of the position he had achieved is shown by his appointment early in 1916 to be consulting physician with the forces in France; he served first in that capacity with the First and Second Armies (C.B. 1917), but a little later, when it became the practice to appoint a consulting physician to each army, he was attached to the Second, with which he

continued in the work of the Ministry of National Service. His special knowledge of skin diseases led to his election to be President of the Section of Dermatology of the Royal Society of Medicine in 1917, of the Section of Dermatology at the Birmingham Meeting of the British Medical Association in 1911. It was shown also by the honorary membership of the French and Netherland Dermatological Societies and the articles that he contributed to works such as *Quaestiones Medicæ* and *Allbutt's System of Medicine*. The wide scope of his interests included medical history as evidenced by his scholarly articles, "The Story of St. Roncevaux" (1907) and "Eleanor of Castile, Queen of England, and the monuments erected in her memory" (1908), published in the *Charing Cross Hospital Gazette* and by his active participation in the work of the Historical Medicine Section of the Royal Society of Medicine.

Galloway's judicious mind, broad outlook, and tact made him an admirable member of committee, and his services were therefore much in request; after the South African

he served on the important advisory committee for Army Medical Services appointed by Mr. St. J. Brodrick (now Lord Midleton) and after his return from France during the European war he was made Chief Commissioner for Medical Services, Ministry of National Service (K.B.E., 1918). In the Royal College of Physicians, of which he became a Fellow in 1897, he was a Councillor (1916–18), President (1920–22), and in addition a member of the Board of Management of the Conjoint Examining Board in London; he thus had much to do with the new arrangements for the curriculum of medical studies.

Sir James Galloway came a member of the British Medical Association in 1891 and served it in many capacities. The first office he held was that of honorary secretary of the Section of Dermatology at the Annual Meeting in Montreal in 1901, and, as already said, he was president of that Section at the Annual Meeting in Birmingham in 1911. He was a member of the Council of the Metropolitan County Branch for many years, was chairman of the Emergency Committee established by that Branch

SIR JAMES GALLOWAY.

[Lafayette, Ltd.

in 1915. He became a member of the Central Council of the Association in 1914 and served in that capacity until 1917. He was a member at various dates of the Finance Committee, the Journal Committee, and the Hospitals Committee, and was also co-opted a member of the special committee of Chairmen of Standing Committees out of which the Central Medical War Committee evolved, as stated more at length below. One of the greatest services Sir James Galloway rendered to the Association was to take the chair at the Conferences of Representatives of the Medical Staffs of Voluntary Hospitals held under the auspices of the British Medical Association in London in 1920, 1921, and 1922. In the chairmanship of these conferences he exhibited skill and power of suasion which contributed in no small measure to the success that attended them. The first conference was called at a time when members of voluntary hospital staffs were profoundly stirred by the grave financial position of the hospitals; it was summoned at such a notice on the action of the Government in appointing a Care Committee, that its constituent members had an opportunity for a preliminary survey of the position and probable effect upon the future, or of familiarizing themselves

country. Yet under these difficult circumstances the conference was handled with a skill that made it as effective and businesslike as a Representative Meeting, where most of the representatives are practised in public business and all are familiar with an agenda prepared and discussed months in advance. That one day's work in December, 1920, gave the Association a sure basis for the evidence which it gave to the Cavo Committee, much of which was accepted by that Committee and has since become the practice of the authorities. In later conferences new conditions brought new difficulties, which were met with equal success. Opinion on points of policy became more sharply defined, and therewith arose the probability of such acute controversy as might destroy the effectiveness of any conference. But with each new occasion the good humour, gentle playfulness, and imperturbability of the chairman brought out in response all that was best in the assembly to most practical purpose.

At the first conference, held on December 31st, 1920, resolutions were passed that the voluntary method of hospital administration should be maintained, that the hospitals should not be rate-aided, and that any Government grant should come through an intermediary channel, that every patient who was not a necessitous person should make a contribution towards the cost of his maintenance, and that a percentage of patients' payments should pass into a fund to be allocated at the desire of the honorary staff. At the second conference, on November 16th, 1921, a resolution was passed in favour of the extension of the services of the hospitals to private paying patients, and it was again resolved that a percentage of payments made by patients to hospital maintenance should be passed into the staff fund. At the third conference, on March 22nd, 1922, a resolution was passed to the effect that the essence of the voluntary system was the independent and voluntary management of a hospital and was not necessarily related to the conditions of service of the medical staffs; the formation of staff funds from a percentage of patients' payments was again approved; and a resolution was passed that the tenure of office of members of the honorary staffs of voluntary hospitals should, where necessary, be modified to allow more and younger practitioners to obtain responsible hospital experience. It will be remembered that the whole matter arising from the resolutions passed at this series of conferences was placed before the Representative Meeting at Glasgow last July, where important decisions were arrived at. During the course of the staff conferences Sir James Galloway took occasion to point out the great benefit afforded to the representatives of the medical staffs of voluntary hospitals by the opportunity of meeting together at such conferences, which were the only chances of consulting on important principles of hospital administration, and the value of the organization of the Association in calling the conferences and making their recommendations effective.

How great is the indebtedness of the profession to Sir James (then Dr.) Galloway in the inception and successful organization of the Central Medical War Committee is known probably to few. From him came the proposal at the Council meeting of the British Medical Association in January, 1915, that a committee of the Association should deal with matters arising from the withdrawal of medical men from civil practice to serve with the military forces. In April of the same year Dr. Galloway became chairman of the War Emergency Committee of the Metropolitan Counties Branch Council, the forerunner in work and ideas of the Central Medical War Committee. Through him the Council of the Association was led to vote money for the purpose of carrying on the work; and when in July, 1915, the War Emergency Committee for England and Wales was appointed Dr. Galloway became a representative of the Council on that body. In this capacity his services were of the greatest value owing to the insight that he had obtained into War Office methods, and the friendships he had formed while serving on the Advisory Committee for Army Medical Services, appointed after the South African war. When early in 1916 Dr. Galloway went to France as consultant with the forces his assistance was temporarily lost to the Central Medical War Committee. Towards the end of 1917 he was brought back to become Chief Commissioner of Medical Services in the Ministry of National Service, which assumed charge on November 18th, 1917. In this capacity Sir James Galloway continued in sympathetic co-operation with the Central Medical War Committee, referred to it all important questions with regard to medical service which the Ministry had to decide, and frequently attended its

meetings himself. Thus it was to the quiet perseverance, unflinching tact, and calm judgement of Sir James Galloway that the Central Medical War Committee largely owed its origin. In the more difficult periods of the Committee's career, Sir James's intimate acquaintance with the Medical Department of the War Office and its chiefs helped to maintain friendly relations; and in the last year of the war, as Chief Commissioner of Medical Services, he held the balance between the efforts of the Central Medical War Committee to maintain sufficient medical attendance on the civil population and the demands of the War Office for additional medical officers.

SIR HUMPHRY ROLLESTON, K.C.B., President of the Royal College of Physicians of London, writes:

Association for many years and in various circumstances, such as committees, examinations, and more recently at the College of Physicians, where his services as a member of the committee of management were of great value, only strengthened the early impression that Galloway was in every respect a most desirable colleague. He could always be depended on to do his share, and often more, of the work—cheerfully, calmly, thoroughly, and with a punctuality sometimes almost startlingly exact and always without obvious hurry. A clear-headed and wisely cautious adviser, he was most kindly in his judgements and slow to express disapproval of others. A good proof of the general esteem in which he was held can be found in the amount of devoted help he so freely gave as "a doctors' doctor." With a genial and unselfish disposition he had the highest ideals of life, and these were so quietly followed that they seemed, as indeed they had become, a natural characteristic of the man. His premature death leaves a gap which it will indeed be hard to fill.

To a former colleague on the Medical Staff of the Ministry of National Service we are indebted for the following tribute:

Of the senior officials of the Ministry of National Service none was regarded with more admiration and personal affection by his colleagues and subordinates than Sir James Galloway, the Chief Commissioner of Medical Services. As the head of perhaps the most pivotal department of a Ministry whose main function was to restore public confidence in the fairness of official dealing with the problems of recruiting—medical and other—he was pre-eminently the right man in the right place, for he commanded alike the confidence of the general public and his own profession. In addition to a wide knowledge and experience of general medicine he brought to his work in the Ministry an intimate acquaintance of the medical aspects of recruiting, while his previous active service in South Africa and in France had given him a first-hand knowledge of army medical organization and requirements. He was thus exceptionally fitted to hold the balance between the ever-conflicting interests of the medical needs of the civilian population and the demands made by the Navy, Army, and Air Force for medical officers. As regards recruiting, the disappearance of the unsatisfactory R.A.M.C. "categories" and the establishment of the M.N.S. "grades," based solely upon the physical condition of the recruit, was a far-reaching improvement. Galloway put an immense amount of thought into the Instructions to Medical Boards regarding the points which were to determine grading, and the resulting document will remain as a monument to him and to the experts whom he consulted. The sectional system of examination by which each recruit was examined by two or three examiners was another improvement introduced by him, and one which went far to establish confidence in the public mind. The extent to which Galloway's personal qualities affected the work of his department to its farthest ramifications is known only to those closely associated with him in it, but it may be safely said that it is in no small measure due to him that there was brought into being a practical and scientific method of medical examination of recruits, superior to anything previously known, which remains ready for immediate application should a similar emergency unhappily arise. In all the turmoil of conflicting currents of social and professional prejudices and political strivings Sir James Galloway maintained an unruffled serenity. He had two great qualities of leadership—the power of detachment, which enabled him to keep a broad outlook over his work as a whole while at the same time he was fully acquainted with details, and the capacity to devote his work to his staff. He made it a rule to keep his own desk free from papers, and the quiet tidiness of

his room was an index to the mind of its occupant, who, however much pressed by affairs, could always make time to bring his clear and sound judgement to bear upon the problems which were perplexing his officers. In the brief leisure of these strenuous months, at meal times and in travelling, Sir James was the most charming and genial companion, enriching his conversation from the stores of his historical and antiquarian knowledge. He won and held, as such a man could not fail to do, the loyalty and devotion of his staff, all of whom will feel a sense of personal loss in his death.

A largely attended memorial service was held in the Church of St. Martin-in-the-Fields, Trafalgar Square, on Saturday, October 21st. The Rev. H. R. L. Shoppard, assisted by the Rev. A. W. Oxford, M.D., and the Rev. M. Griffiths, officiated. The service included the hymns "O God, our help in ages past," and "Abide with me," and Psalms exxi and xxlii. After reading the lesson Dr. Oxford gave a short and deeply impressive eulogium, more especially of Sir James Galloway's work for the patients at Charing Cross Hospital. Among those present, besides Lady Galloway and members of the family, were Sir Humphry Rolleston, President of the Royal College of Physicians, Sir William Thornburn, representing the Council and Court of Examiners of the Royal College of Surgeons, Sir Frederick Mott, Sir James Dundas-Grant, Sir Charles Ballance, Sir Herbert Waterhouse, Dr. William Hunter, Sir James Cantlie, Dr. Arnold Chaplin, Dr. J. A. Ormerod, Dr. Raymond Crawford, and Sir James Porter, together with the vice-chairman of Charing Cross Hospital, and many members of the resident staff, nurses and students. The British Medical Association was represented by Dr. N. G. Horner, Assistant-Editor, *BRITISH MEDICAL JOURNAL*, and Dr. A. D. Macpherson, Assistant Medical Secretary.

LIEUT.-COLONEL PATRICK MURPHY, Bombay Medical Service (retired), was killed in the sack of Smyrna by the Turks on September 13th, aged 78. He was educated at Queen's College, Cork, and graduated M.D. and M.Ch. at the Queen's University, Ireland, in 1868. He entered the I.M.S. as assistant surgeon on October 1st, 1869, became surgeon lieutenant-colonel after twenty years' service, and retired on January 17th, 1895. He served in the Egyptian war of 1882, when he was present at the battle of Tel-el-Kebir, and received the medal with a clasp and the Khedive's bronze star.

The Services.

INDIAN MEDICAL SERVICE.

The New Director-General.

The term of office of the present Director-General of the Indian Medical Service, Major-General Sir William Edwards, K.C.I.E., expires in January next. As his successor has been appointed Colonel Robert Charles Macwatt, C.I.E., the senior colonel on the establishment. Colonel Macwatt was born on January 22nd, 1865, the son of Dr. Robert Charles Macwatt, of Dunse, Berwickshire, so will be 58 when he takes up his new post. He was educated at Edinburgh University, where he graduated M.B. and C.M. in 1886 and B.Sc. in 1897, subsequently taking the F.R.C.S. Eng. in 1911. He entered the I.M.S. as surgeon on October 1st, 1887, became major after twelve and lieutenant-colonel after twenty years' service, and attained the rank of colonel on January 8th, 1918, when he was appointed Inspector-General of Civil Hospitals in the Punjab, the post which he still holds. Almost all his service has been spent in the political department in Rajputana, under the Indian Foreign Office, where he has held the posts of Agency Surgeon successively in Haraoti and Tonk, Kotah, and Jhalawar. In June, 1907, he became Residency Surgeon of the Western Rajputana States, and in November, 1913, of the Eastern Rajputana States; while in September, 1914, he was appointed Chief Medical Officer in Rajputana and Civil Surgeon of Ajmir. He served on the north-west frontier of India in the Hazara campaign of 1898, receiving the frontier medal with a clasp; in the Lushai campaign of 1889 on the north-east frontier (clasp); and again on the north-west frontier in the Hazara and second Miranzai campaigns of 1891, getting a clasp for each. He received the Kaiser-i-Hind medal of the first class on January 1st, 1903, and the C.I.E. on January 1st, 1916, and on March 22nd, 1921, was appointed Honorary Surgeon to the King.

MEMORIAL TO LIEUT.-COLONEL E. M. WILSON.

THE memorial to the late Lieut.-Colonel E. M. Wilson, C.B., C.M.G., D.S.O., R.A.M.C., will be unveiled on Friday, November 3rd. A short service will be held by the Right Reverend Bishop J. Taylor Smith, C.B., C.V.O., D.D., Chaplain General to the Forces, in the chapel of The Queen Alexandra Military Hospital, Millbank, at 4 p.m. Lieut.-General Sir John Goodwin, K.C.B., C.M.G., D.S.O., K.H.S., Director-General, Army Medical Services, will perform the unveiling ceremony. All ranks of the Royal Army Medical Corps are invited to attend. Dress: Service dress with swords; mourning bands will not be worn.

THE third annual dinner of the medical officers of No. 14 Stationary Hospital will be held on Friday, December 8th, at the Trocadero Restaurant, Piccadilly, at 7.15 for 7.45 p.m. Colonel C. R. Evans, D.S.O., will be in the chair. The price of the dinner will be 15s., exclusive of wines. Evening dress or dinner jacket, miniature medals optional. The honorary secretaries are Major H. M. Perry and Dr. H. L. Tidy, 39, Devonshire Place, W.

Medical News.

THE Board of Trade has appointed Sir Thomas Robinson, M.P., to be chairman of the Dyestuffs Advisory Licensing Committee set up in January, 1921. It has also appointed Mr. R. Waddington, M.P., and Professor G. T. Morgan, F.R.S., to be members of the Committee.

THE annual meeting of Fellows and Members of the Royal College of Surgeons of England will be held at the College, Lincoln's Inn Fields, W.C., on Thursday, November 16th, at 3 p.m.

THE annual series of post-graduate lectures and demonstrations at the Royal Salford and Ancoats Hospital, Manchester, commenced on October 19th. The meetings take place on Thursday in each week, at 4.30 p.m., alternately at the two hospitals, the next—on November 2nd—being at Ancoats Hospital, when Dr. Arnold Renshaw will lecture on diabetes.

LADY CONSTANCE MELVILLE, who died in August last, has by her will bequeathed £4,000 to Dr. H. A. des Voeux, of Buckingham Gate, "in grateful thanks for his untiring help to a very troublesome patient."

THE next session of the Dental Board of the United Kingdom will commence at 2 p.m. on Tuesday, November 14th, when the chairman, the Right Hon. Francis Dyke Acland, M.P., will take the chair and give an address. The Board will continue to sit from day to day until the termination of its business.

THE old students' dinner of St. Thomas's Hospital will be held on Friday, November 10th, at the Princes' Restaurant, Piccadilly, at 7 for 7.30 p.m. The chair will be taken by Sir Charles Sherrington, G.B.E., M.D., President of the Royal Society.

A SHORT course of seven lecture-demonstrations on gastrointestinal affections in children will be given at the Children's Clinic, Western General Dispensary, Gosway Street, near Edgware Road station, on Mondays and Thursdays at 4.45 p.m., from November 2nd to 23rd inclusive. The first lecture, with experimental illustrations, will be given by Professor Sir William Bayliss, followed by six practical demonstrations by Dr. Bernard Myers. The fee for the course is one guinea, tickets for which and copies of the complete syllabus can be obtained from the secretary to the Fellowship of Medicine at 1, Wimpole Street, W.1.

THE British Orthopaedic Association met in London on October 20th, when a number of papers were read. The members dined together that evening at the Langham Hotel. The President, Sir Robert Jones, who was in the chair, after declaring that there were to be no speeches, called on one member of the company after another to speak. One of his victims was M. Calvé and another Dr. Mark Jansen, who promised the association a very cordial welcome from his fellow countrymen when it visits Leyden next spring. On Saturday morning a visit was paid to the Royal College of Surgeons, when Sir Arthur Keith and Mr. Lawford Knaggs gave a demonstration chiefly concerned with deformities and lesions of the bones.

THE late Dr. Henry Edward Langford of Kidderminster, who left estate valued at £16,451, has by his will directed that after some family legacies the residue of his estate on the death of his widow is to go to the Lifeboat Institution to the extent of £5,000, and the remainder, which it is expected will amount to about £7,000, to the Chancellor of the Exchequer towards the expenses of the late war.

It was announced recently that the Allied Chemical and Dye Corporation of New York has instituted in perpetuity an award of 25,000 dollars annually, to be presented to the chemist in the United States who has contributed most to the benefit of science and the world; the gift is not limited to any particular field of chemistry.

THE British Medical Association Council dinner on Wednesday last (the first of its kind) was well attended and in every way successful. The President of the Council, Dr. R. A. Bolam, was in the chair, and the toast of the commonwealth was given by Sir William MacEwen, President of the Association. It was acknowledged by Sir Arthur Robinson, Chief Secretary of the Ministry of Health, and Sir Anthony Bowley, President of the Royal College of Surgeons of England. The health of the ex-President, who was the guest of the evening, was given by Dr. Wallace Henry, Chairman of Representative Meetings, and suitably acknowledged by Dr. David Drummond. The toast of the guests was given by the Chairman and responded to by Mr. E. Shortt, K.C., M.P., and Sir Henry Craik, M.P.; the health of the Chairman was proposed by Sir Jenner Verrall and briefly acknowledged. We propose to publish a more detailed report in our next issue.

DR. HENRY HANSON, who was formerly health officer at Panama, and at one time bacteriologist to the State of Florida, U.S.A., has just completed a successful campaign against yellow fever in Peru, and is now advising as to the reorganization of the public health services of that country with the view of eradicating malarial plague.

FOR a quarter of a century the Anglican Sisterhood known as the Community of St. Peter has, among its charitable activities, kept up a home for aged and infirm women needing nursing and care, called St. Peter's Harbour. The home is self-supporting, but is found to be too small to accommodate the many applicants for admission. A public appeal is, therefore, being made—the first for sixty years—for funds to purchase a larger suitable house. Contributions should be sent to the Sister in Charge, St. Peter's Harbour, 10, Greville Place, N.W.6.

A SESSIONAL meeting of the Royal Sanitary Institute will be held at the Town Hall, Wallasey, on Friday and Saturday, November 3rd and 4th. Dr. F. T. H. Wood, M.O.H. Bootle, will open a discussion on "The expenditure of public money on health: why it is worth while." The chair will be taken by Professor H. R. Kenwood, C.M.G., at 7.45 p.m.

MR. MARMADUKE SHEILD, consulting surgeon to St. George's Hospital and, early in his career, house-surgeon to Addenbrooke's Hospital, Cambridge, left the residue of his estate, after paying certain specific legacies and subject to the life interest of his sister, to the medical school of the University of Cambridge, to found a Marmaduke Sheild Scholarship in Human Anatomy, and the balance for the general purposes of the medical school. The value of the net personally was £91,452. Mr. Sheild graduated M.B., B.Ch.Camb. in 1883.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

ACTIONS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, Medisecra, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Circular Road, Dublin; telephone, 4737.
4. Bacterius, Dublin; telephone, 4737.
5. Rutland Square, Edinburgh; telephone, 4361, Central.

QUERIES AND ANSWERS.

INCOME TAX.

"X. Y." bought a death vacancy practice in December last.

He is chargeable with tax as from the date when he began to be entitled to the receipts, and the executors of the late proprietor are liable up to that date. The assessment for 1922-23 must be made on the average amount of the profits of the three years 1919, 1920, and 1921; but "X. Y." has the right of having that assessment adjusted at the end of the year on his applica-

or by reason of his succession to the practice. It should be borne in mind, however, that for that purpose he will have to bring in his full and not merely his cash profits, the latter being an insufficient index of the true income from the practice in his early years.

"T. B." replaced his old Ford car by a new Overland, receiving as much for the former as it had cost him.

In evidence given by the official witnesses before the Royal Commission on the Income Tax it was stated that where an improvement was effected in connexion with a replacement the proper basis of allowance was the net cost that would have been incurred by the purchase of a similar machine. Consequently in this case "T. B." is entitled to the excess of the price of a Ford as at the date the Overland was purchased (£295) over the amount allowed to him (£155)—that is, £140 net.

IS DESQUAMATION AFTER SCARLET FEVER INFECTIVE?

A CORRESPONDENT asks us to answer the question, Is the desquamation of scarlet fever infections; or, putting it another way, Is the peeling child a danger to the unprotected?

We are not prepared to give a definite answer to the question, whichever way it be put, and so far as we can ascertain no definite opinion has been expressed by the Ministry of Health or previously by the Local Government Board. Everybody is agreed that discharges from the nose, throat, or ears may be infective, as also any discharge from a cutaneous lesion, as, for instance, cracked ears; probably the general opinion of public health officers is that desquamation may be disregarded as unimportant from the aspect of infectivity. Some authorities among whom we may mention Dr. Robert Milne, while holding this view, consider that special precautions should be taken by way of applications to the skin.

LETTERS, NOTES, ETC.

PREVENTION OF VENEREAL DISEASE.

"SEXEN" writes: May I ask your readers to consider the position set up by "G.", whose letter you print on page 765? Does he consider that it is the duty of the employer to inquire how much it costs his servant to live? Is the employer to fix the standard of living for his servant? Does he suppose that shareholders receive dividends as shares in profits or as sinking fund? Does he not know that wages must be a first charge on the gross profits—a charge often so heavy that the balance is carried to the wrong side of the profit and loss account? If he thinks that: reasonable self-love is inadequate to produce a decent society, will he turn to Bishop Butler's *Analogy*, the greatest work produced by a churchman in a sceptical age; or perhaps the work of Bentham (*Principles of Morals and Legislation*) some fifty years later may serve his turn. Does he himself propose to take from his practice only enough to pay expenses and secure an old-age pension and hand over the rest to some visionary society for assisting those who cannot or will not help themselves?

SAMPLES AND RETURNS.

"W." writes: The emphasis laid by the Section of Obstetrics at the Glasgow meeting on the necessity of examining the urine reminds me of the old Scottish doctor's advice to his youthful successor:

Old Doctor: And mind this—aye ask your patients to send you a sample of their urine.

Young Doctor: Oh! How could I do that in a case of broken leg, for example?

Old Doctor: Doesn't matter! Broken leg or broken head, make them send their urine. It's the only chance you'll have of getting your bottles back!

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 33, 36, 37, and 38 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 34 and 35.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 767.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

It is against the rules of the Post Office to receive poste

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

310. Systemic Blastomycosis.

J. R. WILLIAMS (*Med. Journ. of Australia*, August, 1922, p. 185) reports a case of systemic blastomycosis due to a pathogenic yeast. The patient gave a history of influenza and bronchitis, and was admitted to hospital suffering from meningitis, which, on account of its chronic character and the clear appearance of the cerebro-spinal fluid removed by lumbar puncture, was attributed to a tuberculous lesion, this being supported by the existence of a patch of consolidation at the base of the right lung. But microscopic examination of the cerebro-spinal fluid revealed the presence of large numbers of oval cells, slightly larger in length than polymorphonuclear leucocytes: on incubation these cells showed budding, and after three days' culture on blood agar yielded a moist sticky growth of yeast cells. The patient was in hospital twenty-nine days, and the course of the disease was a gradual decline, unaccompanied by any fever. At the post-mortem examination the lower lobe of the right lung was found to be partly consolidated and partly collapsed, the surface being lumpy and irregular. Scrapings from the cut surface showed the parasite in countless numbers under the microscope, and sections of the affected area revealed vast aggregations of the parasite surrounded by a network of damaged lung tissue with fibrotic changes. On removing the brain excess of sticky cerebro-spinal fluid was noted, and the subarachnoid area contained little patches of glue-like excretion in the poutine area; on section the brain presented multiple minute abscesses close to the cortex. A study of the morphological characters of the parasite showed that the most typical cell was an elongated cellule, pointed at one end and rounded at the other, containing two refractile bodies and surrounded by a well-defined double-contoured capsule. Cultures were most easily obtained in blood agar, and in this medium the organism grew in a circular form, the individual cells varying considerably in size, but being on the average much smaller than the cells observed in the tissues. Not all the laboratory animals inoculated with cultures developed lesions, but in one rabbit the kidneys were found to be large and granular, and on section the parasites were easily discoverable in the renal tissue. Although it is known that there are many varieties of pathogenic yeasts blastomycotic lesions of the nervous system have only rarely been reported.

311. Treatment of Hypertension.

N. B. FOSTER (*Journ. Amer. Med. Assoc.*, September 30th, 1922, p. 1089) contributes a study of definite disease groups wherein some type of hypertension is a symptom. The most common disorder under this heading is nephritis. The principle which is most likely to be useful in the management of this disorder, he says, is to regard vascular hypertension in this group of cases as a symptom of an intoxication. These cases progress to cardiac disorders and vascular accidents. Having in mind the usual course of events, it is necessary to correct the disorder in its earliest stage—the only stage in which restitution to normal can be expected. It is essential not only to know the details of the physical state of the patient so far as it is possible to know them, but also to become acquainted with the temperament and the habits of the patient, especially in respect to work (both physical and mental), food, and sleep. The primary object in regulating the treatment is to correct modes of life which are unwholesome. In the case of the person who has been accustomed to little or no exercise it becomes necessary to increase the exercise gradually until he is able to do as much as a person of his age should do. His diet should be regulated according to his proper weight and not according to his real weight; that is to say, if a person weighs 200 lb., and his proper weight for his height is 180 lb., his diet should be on the basis of maintaining his weight at 180 lb. As a general rule, the treatment of hypertension cannot be carried out successfully at home. It is Foster's belief that early cases of hypertension should be treated in special sanatoriums. The mental atmosphere is primarily one of sport; vigorous exercise is the rule, but in the form of games and of sports rather than in the form of gymnastic exercises. Under a regimen in this sort of atmosphere the patient receives a kind of re-education. Physically, the flabby individual becomes hard, and all his bodily functions are toned up accordingly. Instead of consuming more calories in food each day than he expends, he will, for a period, expend more than he consumes and lose weight in

consequence. When it is possible to secure the co-operation of patients so that one may carry out a careful regimen through a sufficiently long period of time, high blood pressure in early cases is susceptible of cure. The chief obstacles to treatment are, first, that the patient will not co-operate because he still feels perfectly well at a stage in his disorder when treatment offers the best prospect of a successful issue. The second obstacle is economical, in the sense that relatively few persons can afford to devote themselves exclusively, for a number of months, to the cultivation of their health. When the patient cannot give up enough of his time to carry out a routine such as that outlined, the best compromise consists in directing therapeutic effort to the adjustment of the diet, so that it shall be adequate for the patient but not too much; and secondly, regulating the life of the patient to ensure as much exercise and diversion as is compatible with his necessary routine activities. The observation of a large number of cases of hypertension has led Foster to believe that the disorder is far more common among those of sedentary occupations than among persons who do vigorous manual labour. Many cases of hypertension come first under observation at a period when the heart is already seriously damaged and when a considerable degree of arterial degeneration and sclerosis is detectable. Many of these patients also have a serious impairment of the renal functions. At this stage in the disease little or nothing can be done for the treatment of hypertension. The best that can be hoped for is to diminish in some degree the burden on the labouring heart.

312. Antityphoid Vaccination in the German Army during the War.

R. PFEIFFER (*Arch. de med., cir. y esp.*, Juno 10th, 1922, p. 433) states that as early as September and October, 1914, there was a considerable rise in the typhoid mortality in the German army, the maximum of 0.5 per thousand being reached in December. There was then a marked drop, 0.02 per thousand being reached in July, followed by a rise to 0.06 per thousand in September and October, 1915. Subsequently the epidemic, which had threatened to be serious, became practically extinct, the typhoid mortality during the following years of the war being about 0.01 per thousand, which corresponded approximately to the statistics of peace time. During the first year of the war (August, 1914, to August, 1915) there were 8,065 deaths from typhoid; in the second year the deaths numbered 1,909, and in the third year fell to 632, while in the last year they rose again to 1,031, because at this stage of the war the physical value of the men called up was very inferior. The marked drop in the incidence of typhoid can only be attributed to antityphoid vaccination. The hypothesis that the typhoid bacillus had lost its virulence after the first few months of the war is quite unfounded and is shown to be erroneous by the fact that in certain areas the vaccinated troops remained immune while an epidemic of typhoid developed among the non-vaccinated civil population. Moreover, in that part of the Austrian army in which inoculation was delayed until 1915 typhoid retained its virulence, and it was only after the introduction of inoculation that the epidemic assumed a mild character like that in the German army after March, 1915. Although some cases among the inoculated were severe, such cases were exceptional. Whereas in the non-vaccinated the mortality ranged from 12 to 20 per cent., in the vaccinated it did not exceed 2 to 3 per cent. and sometimes fell to zero.

313. Itchy Points (*Puncta Prurítica*).

N. TOOMEY (*Arch. Derm. and Syph.*, June, 1922, p. 744) describes a rare type of itching, frequently confused with tic and neurotic scratching, but differing in distribution, character, and appearance. The lesion is limited to one or more minute points, each apparently smaller than the point of a steel pin, and, unless manipulated, presenting no change from the normal, and not giving rise to excoriations, since titillation and pressure, rather than scratching, affords most relief. The attacks, lasting from ten minutes to an hour, may occur several times during the twenty-four hours, with several weeks' interval of freedom. While usually occurring in the skin over a bony prominence they may appear on the abdomen, calf, and lateral aspects of the thigh and leg. The areas of skin most frequently involved are those over the helix of the ear, forehead, malar eminence, lateral aspect of the nasal bone, lower border of the mandible, scapular spine, distal thirds of the ulna and radius, styloid processes, carpo-phalangeal joints, lower ribs, crest

the ilium, sacral prominences, femoral trochanters and condyles, malleoli, and first joint of the great toe. The etiology is unknown, but intestinal toxæmia and alcoholic and sexual excesses appear to precipitate, if not actually cause, such attacks. The diagnosis from such conditions as incomplete herpes, dermatitis herpetiformis, pruritus, seborrhoeic dermatitis, prurigo, lichen planus, and neurotic itching rests upon such features as the minutely circumscribed nature of the affection, absence of vesicles, etc. Local applications are useless, a strong monothion lotion, for example, only affording temporary relief. Any intercurrent toxæmia requires treatment, two patients with fermentative enteritis becoming cured concurrently with the cure of the enteritis. The administration of 20-grain doses of sodium thiosulphate, well diluted, after meals effected a cure after a three months' course in one patient in whom it was tried.

314. Tincture of Hyoscyamus and Hyoscyne in Paralysis Agitans.

MM. REBATTU, MOLLON, and SEDAILLAN (*Journ. de Méd. de Lyon*, June 5th, 1922, p. 342) state that hyoscyne and tincture of hyoscyamus given in many cases of paralysis agitans, of athetosis, and of chorea have had the following results: (1) Hyoscyne in injection may be dangerous (poisoning has followed a dose of 0.5 mg.). Its effects on tremors and insomnia have been transient, symptoms returning when treatment ceased. (2) Hyoscyne by the mouth is better borne (1 mg. is the maximum dose). It has no action on tremors, and only slight effect on insomnia. (3) Hyoscyne given with tincture of hyoscyamus has caused cessation of tremors for three days, disappearance of pain, and return of sleep. (4) The tincture given alone diminishes slightly tremors and pain, increases sleep and sense of well-being, and is better borne by patients. (5) Contrary to Erb's statements, heart disease does not appear to contraindicate the use of hyoscyne. It has been well borne by two patients, one of whom had mitral incompetence and the other had permanent bradycardia. (6) Hyoscyne given by the mouth in two cases of athetosis and one of chorea has not affected the movements.

315. Bismuth Poisoning and Albuminuria.

PAUL BLUM (*Paris Médical*, July 29th, 1922, p. 105) observes that stomatitis and other forms of bismuth poisoning have again attracted attention since the discovery of the antisyphilitic action of certain bismuth salts. Stomatitis appears to have been most frequently observed, although gastrointestinal, renal, and hepatic lesions have been described. Although several eminent French authors have seen no other effect on the kidneys than a transient polyuria, others have described cases of syphilis under treatment by intravenous injections of bismuth salts, who developed quite suddenly severe albuminuria, followed by the passage of epithelial, granular, and hyaline casts. The author has collected numerous cases, from the time of Pott (1739) onwards, in which there was intolerance of bismuth salts, especially after their external application. Toxic symptoms have been observed after the application of bismuth subnitrate (to varicose ulcers, burns, etc.), which forms a soluble albuminate in contact with a raw surface. The oxygallate (airol) and subgallate (dermatol) and Beck's paste have all produced toxic effects, and these have followed the injection of bismuth emulsion in cases of fistula, either for radioscopy or when treating cloacæ. A number of writers have observed stomatitis, black patches on the gums and tongue, enteritis, and albuminuria (occasionally). Eggenberger has published a fatal case in a child of 7. Reich and Matsuoka have recorded fatal cases in which renal lesions were found at the autopsies. Internal administration of bismuth is far less dangerous, but cases have been recorded when the subnitrate has been given for gastric ulcer or for skiagraphic purposes. The symptoms recorded suggest that the presence of nitrites is responsible. Poisoning from bismuth carbonate is much more rare, though its conversion into a soluble chloride in some instances was noted by Chassovant. Blum gives details of numerous experiments on animals with various double salts. The renal lesions observed were not exceptional—albuminuria, casts, and parenchymatous nephritis, with more or less fatty degeneration. In animals, as in man, renal lesions coexisted with stomatitis and enteritis. Pisciotti compares the action of bismuth to that of phosphorus and antimony. Bismuth is eliminated as sulphide, which explains the fact that certain urines are black, resembling that of hæmoglobinuria, although there is no renal lesion. Blum emphasizes the point that, clinically and experimentally, the lesions in the mouth and intestine are the first signs of bismuth poisoning—they are danger signals which indicate the necessity for a systematic examination of the urine. In syphilis, during a course of bismuth treatment, it is especially necessary to examine the urine systematically, as when the patient is undergoing treatment with mercury or arsenic. Should one pay attention to a slight albuminuria? In the author's

opinion it should not be considered of toxic origin unless accompanied by the above-named symptoms; in certain cases it may be a "Herxheimer's reaction," indicating the continuance of the treatment rather than its cessation. Thus, Fournier and Guénot have obtained excellent results in the treatment of syphilis while disregarding very slight albuminuria. In toxic albuminuria, bismuth treatment should be stopped immediately, and thus the possibility of more serious results may be avoided.

SURGERY.

316. Disabilities of the Hand and Wrist.

W. A. COCHRANE (*Edinburgh Med. Journ.*, September, 1922, p. 97) points out that disabilities of the hand and wrist form an important group of cases, and their care must be based upon the anatomical data, of which he attempts to give an analysis. The hand presents three arches, one longitudinal and two transverse, and the thumb stands in relationship to all of them. The integrity of the longitudinal arch may be impaired after fracture of one of the inner metacarpals; this results in limitation in full flexibility of the metacarpophalangeal joints, and a form of claw hand may develop. This is due to the lumbricals and interossei having to operate at a disadvantage. With regard to the thumb, the basal joint is the big factor in relation to function and range of motion of this digit. A thumb in the position of adduction and extension is fatal from a functional standpoint, and in splinting abduction and opposition must be secured. The transverse arches are proximal and distal, depending on the carpal bones and the heads of the metacarpals. In the examination of crippled hands, the loss of the arches, joint stiffness, and tendon stiffness form a trinity of difficulties. In any disability of the hand after reduction of the deformity the member should be placed with the wrist slightly dorsiflexed, the thumb in full abduction and rotated into opposition, while the metacarpophalangeal joints are slightly flexed. In Colles's fracture complete reduction is of first importance. Twelve to sixteen days' immobilization is the routine practice, somewhat shorter in the aged, the hand being fixed in moulded plaster splints, flexed, pronated, and with ulnar deviation. The scaphoid and semilunar are the bones most frequently fractured in the carpus; in dislocation it is usually one of the bones of the proximal row that is affected. Fractures are treated on a cock-up splint and usually unite satisfactorily. In compound fractures the wrist must be treated in dorsiflexion, whether ankylosis may supervene or not. Fracture of the metacarpals leads to shortening, and should be treated by finger traction. Stiff fingers may be treated by incisions in hot or cold water. In severe cases forcible manipulations should never be attempted. A policy of traction and distraction is instituted by prolonged finger traction until evidence of joint separation is seen by depression of the skin and the x-rays. This, combined with massage, gives good results and shows almost no tendency to recurrence of stiffness.

317. Voluntary Diplopia.

O. BALDOZZI (*Il Policlinico*, Sez. Prat., July 17th, 1922, p. 946) records two cases of voluntary diplopia, the mechanism of which differed in each patient. The first patient, by contracting each external rectus separately, produced a crossed diplopia, while the second was able to contract each internal rectus separately, giving rise to homonymous diplopia. There was thus a voluntary dissociation in movements which are normally synergic. The possibility of dissociating synergic movements, which is so rare in the ocular muscles, is more frequently found in the frontalis muscle, whose two halves, which usually contract synergically, may be dissociated in some subjects, so that they contract separately. In the cases described by Baldozzi the nuclei of the third and sixth nerves are closely connected by fibres which run in the posterior longitudinal bundle and maintain the functional synergy of the respective muscles. In the first case the nucleus of the sixth nerve and in the second case the portion of the nucleus of the third nerve belonging to the internal rectus are freed from their physiological interdependence on receiving the usual stimulus from the cerebral cortex.

318. Facial Paralysis from Cauterizing with Chromic Acid.

T. V. LIEBERMANN (*Deut. med. Woch.*, July 7th, 1922, p. 905) points out that the practice of cauterizing granulation tissue with chromic acid in the neighbourhood of the facial nerve is dangerous, and he records a case in which paralysis of this nerve was traced to poisoning with chromic acid. The patient was a man, aged 32, operated on for acute mastoid disease. As the operation wound did not heal satisfactorily, the granulations which had formed were touched with chromic acid under cocaine anaesthesia. During this

procedure the chromic acid rod slipped out of the holder on to the surface of the wound, and the irrigation of the wound, which was at once adopted, was followed by paralysis of all the branches of the facial nerve. This paralysis passed off in an hour, but next day it had returned, and on the patient's discharge from hospital the paralysis was practically complete. Probably the chromic acid first caused transitory paralysis of the facial nerve by direct chemical action on its trunk, and later caused permanent paralysis by provoking necrosis of the bone in the neighbourhood of the nerve.

349. Injuries of the Shoulder.

A. GIBSON (*Journ. of Bone and Joint Surgery*, July, 1922, p. 552) points out that pain in the shoulder region is an exceedingly common condition. The influence of minor injuries to the brachial plexus in shoulder-joint injuries does not appear to have been emphasized. Injuries to the brachial plexus may be of minor degrees only, with slight atrophy of the infraspinatus at one limit to slight wasting of the thenar and hypothenar eminences at the other in cases of cervical rib. The violence may be directly or indirectly applied to the shoulder. If a fracture is present it absorbs the surgeon's attention, and accompanying conditions are subsidiary. Many cases with no fracture show pain and limitation of movement for perhaps months. Painful shoulder-joint is not uncommon following a fall on the hand; the violence has been directly transmitted to the humero-scapular articulation, bruising the articular surfaces, and time is required for the repair of the damaged tissues. After accidents resulting from a fall on the shoulder the condition may improve for a time, but the shoulder may remain painful and disabled for many months, sometimes permanently; there may be atrophy of the deltoid and spinati, and these muscles are tender. Most frequently this involvement of muscle and long-continued tenderness is the result of damage to the upper trunk of the brachial plexus. This is, in fact, a minor degree of Erb's paralysis, and the lesion arises from a haemorrhage into the sheath to actual rupture of the nerve fibres. The treatment of these conditions should be rest, only little active movement being permitted; massage and electricity are useful adjuncts.

320. Ligneous Perinephritis.

MAREO (*Annali Ital. di Chirurgia*, July, 1922, p. 281) reports a case of this uncommon disease. A man, aged 31, was admitted into hospital on December 7th, 1913, with a history of slight pain in the right loin for the last six weeks, temperature 38° to 38.5° C., no shivering, no disturbance of micturition. The liver and spleen were normal, the complexion pale; slight sweating was more or less constant. There was a large hard mass in the right flank, no fluctuation. The tumour did not move with respiration and was dull on percussion. Cystoscopy showed a normal bladder, but no urine came from the right ureter. The urine had a specific gravity of 1028, acid reaction, no albumin or mucopus, no sugar, urea 16 per cent., abundant urates. The daily amount passed averaged 1,000 grams. The mass was explored on December 11th, 1913, and found to contain a few drops of pus, in the hard woody mass. Except some slight congestion the kidney appeared healthy. The swelling gradually disappeared, with free suppuration, in about three weeks, and the patient was quite well in forty days. Cystoscopy twenty-five days after operation showed urine passing normally from the right ureter. There was no history of any infective focus either in the tonsils, intestines, or kidney.

321. The Treatment of Acute Osteomyelitis.

G. BRANDT (*Deut. med. Woch.*, July 21st, 1922, p. 972) has investigated the records of the 304 cases of acute osteomyelitis treated under various surgeons in the past twenty years in the surgical department of the University Hospital in Halle. He classified these cases according as they were treated by simple incision of the periosteum or by resection of bone in an attempt to provide free drainage from the interior of the infected bone. In the first class there were 89 cases, with a mortality of 17.97 per cent.; in the second class there were 170 cases, with a mortality of 29.41 per cent. The remaining cases were either not operated on because they were moribund, or they were treated first by incision and later by resection of bone. After eliminating the cases which were already pyaemic or suffering from other complications before treatment could be instituted the author still found that the mortality for simple incision was far less than for resection, being 7.59 and 16.66 per cent. respectively. With regard to post-operative complications, he found that pyarthrosis occurred in 8.8 per cent. of his resection cases, and only in 4.7 per cent. of his incision cases. Metastases in other bones, or in the soft tissues, followed resection in 13.5 per cent., and incision only in 6.7 per cent. Classifying

his resection cases according as this operation was performed early or late in the disease, the author found the mortality was 42.1 per cent. within the first five days, and only 13.3 per cent. when resection was performed after the fourteenth day. The conclusion to which he comes is that in most cases of acute osteomyelitis it is better to confine operative treatment to simple incision of the periosteum than to open up the bone itself.

322.

Disorders of Dentition.

J. COMBY (*Journ. de Méd. et de Chir. Prat.*, July 10th, 1922, p. 457) deprecates the popular belief that the eruption of the teeth can give rise to or aggravate a series of morbid conditions to which infancy is liable. He quotes with approval the aphorism uttered forty years ago by H. Roger, one of the leaders of paediatrics in France—"the disorders of dentition do not exist." The author gives a number of historical instances of this widespread belief and supplements this with numerous examples occurring in his own practice during a period of forty years. Comby regrets that many experienced practitioners appear to take the line of least resistance and give way before the eloquence of an excited mother "who demands that the child's gums shall be lanced," whereas he is convinced that patient investigation of the case of any child suffering from fever, catarrh, diarrhoea, etc., so frequently attributed by relatives to dentition, would show the true origin of the disease. He quotes the case of a child seen in consultation last winter: "A child of 1 year, suffering for six days from influenzal bronchopneumonia with a temperature of about 40° C. Other cases were in the house, and the mother, convalescent but still coughing, begged the medical man to lance the child's gums, although he had eight teeth and had no dental symptoms. The author passes in review cases of "teething cough" and "dental asthma," which have no better foundation than the preceding instances. He refers to acute dermatoses, attributed to dentition, and states that the greater part of these are "toxicodermias"—"nevertheless the mother is obsessed by that idea of dentition which she believes to be supremely dangerous." In the same way, infantile neuroses—insomnia, enuresis, convulsions, and epilepsy—are often attributed to dentition. After giving numerous other examples of this widespread popular belief, the author concludes by reiterating Roger's aphorism—"the disorders of dentition do not exist."

OBSTETRICS AND GYNAECOLOGY.

323.

Ovarian Grafts.

F. DE BRUYNE (*Gynéc. et Obstét.*, 1922, vi, 2) records the clinical experience of the Gand clinic with respect to 58 cases in which, after subtotal hysterectomy with bilateral salpingo-oophorectomy, two portions of ovarian tissue taken from the organs removed were implanted, one on each side, subcutaneously in the abdominal wall at the level of the anterior superior spine. In 28 cases the grafts during the course of the next six to eighteen months became palpable, or no larger than a pea; in 13 cases the graft of one side and in 17 cases that of both sides underwent hypertrophy. The hypertrophied ovarian tissue caused considerable inconvenience to the patients, but was in a favourable situation for easy removal if necessary. In certain instances it was possible to diminish for a time the size of the enlarged cystic graft by external compression. More or less regular crises of congestion of the hypertrophied grafts occurred in many patients. With regard to the effect of the grafting, it was found that symptoms of precocious menopause following operation were absent in 88 per cent. of those with bilaterally and in 69 per cent. of those with unilaterally successful grafts, as against about 29 per cent. of those with no grafts and of those in whom the grafts were palpable or very small. It was found that the frequency of the occurrence of hypertrophy of the implanted fragment varied according to the zone of the ovary from which it was taken; grafts of the cortical zone were most frequently and of the corpus luteum least frequently successful, while medullary grafts were scarcely more often successful than those of the corpus luteum. Signs of ovarian insufficiency were absent in all of the nine patients in whom the graft of each side was composed of cortical tissue. The writer describes the histological finding, in an ovarian graft extirpated two months after implantation, of cystic hypertrophy, attributed to abnormal production of lutein tissue. The cases in general showed hypertrophy of the graft to be relatively more common when it was taken from ovaries of normal microscopical characters. Grafts taken from subjects aged more than 40 were never found to undergo hypertrophy. Transplanted follicles are regarded as being principally concerned in the beneficial effects of the grafting.

321. Diagnosis of Viability.

ACCORDING to L. DROSIN (*New York Med. Journ. and Med. Record*, July 5th, 1922, p. 20), foetal death taking place early in the period of gestation is followed by cessation of the growth of the uterus and of enlargement of the abdomen (if this has occurred); in some cases by secretion of milk; and sometimes by subjective symptoms such as pelvic discomfort, anorexia, and chills. When death takes place in the later months foetal movements and foetal heart sounds disappear, and after a time the uterus shrinks in size, and there is loss of resiliency and crepitation of the foetal skull. Maternal albuminuria, peptonuria, or acetoneuria may usually be detected. It is quite possible for all foetal movements to be suspended, the results of auscultation of the foetal heart to be negative, the foetal movements to be absent or undetectable, and for the child nevertheless to be still alive; in such cases the continued foetal life can only be established by repeated palpation and auscultation, and repeated uterine and abdominal measurements. The writer describes two diagnostic measures which in his hands have proved to be useful. In the first the mother is made to hold her breath after a deep expiration; after ten or fifteen repetitions the diminished aeration of the foetal blood leads, it is stated, to more or less active foetal movements. In the second manoeuvre upward and backward pressure is made firmly on the anterior foetal shoulder; in a large number of cases, especially if the abdominal wall be not too thick, wriggling movements of the shoulder and of the whole foetal body follow.

325. Foetal Post-maturity.

ACCORDING to C. B. REED (*Southern Med. Journ.*, 1922, xv, p. 286), mature babies measure from 48 to 53 cm. in length and weigh from 5 to 9 lb. Measurement of the foetus *in utero* is more certain than pelvimetry. By Ahlfeld's method the distance between the upper foetal pole and the maternal symphysis is measured by the pelvimeter, and after deduction of 2 cm. for the thickness of the abdominal wall the measurement is multiplied by 2; in Reed's experience this estimate of the foetal length corresponded exactly with the *post-partum* figure in 37 per cent. of cases. By Perrot's manoeuvre the foetal head, lying across the pelvic inlet, is measured from occiput to frontal bone; the biparietal measurement is inferred by deduction of from 2.5 cm. to 1.5 cm., in correspondence with the occipito-frontal dimension obtained. McDonald determines the month of pregnancy by measuring from symphysis to fundus in centimetres and dividing by 3.5. All these methods are unsatisfactory in cases of obesity and hydramnios. Not all babies weighing 9 lb. or more are post-mature, although according to Winckel 78.4 per cent. have passed the estimated date of their maturity.

326. Foetal Measurements.

L. A. CALKINS (*Amer. Journ. of Obstet. and Gynec.*, August, 1922, p. 109), from measurement of 369 foetuses preserved in formalin, ranging in length from 23 to 544 mm., has constructed formulae by which, any single foetal dimension being known, it is possible accurately to estimate the external body proportions of the foetus at any stage of development. Measurements of the head, he finds, plotted as ordinates against standing heights (crown to heel) as abscissae give a graph which is a straight line. The relationship between any two dimensions can be expressed by the formula $y = ax \pm b$, x and y being body dimensions and a and b constants. It follows that by accurately determining any one body dimension *in utero* the size of the foetal head can be deduced; an x-ray technique suitable for the purpose is now being sought by experiment. From his measurements the author is led to believe that birth-moulding effects greater changes in head dimensions than is usually believed.

PATHOLOGY.**327. Tetanus Bacillus in Intestines of Man.**

CARL TENBROECK and J. H. BAUER (*Journ. Exper. Med.*, September, 1922, p. 261) were able to demonstrate the presence of tetanus bacilli in 34.7 per cent. of stools from 78 individuals in Peking. A suspension of the stool to be examined was treated at 80°C. for twenty minutes to destroy the non-spore-bearing organisms, after which 1 c.cm. of the suspension was transferred to sugar-free broth containing a piece of sterile rabbit kidney or spleen in a fermentation tube. After four days' incubation films were made from the sediment in the tube and searched for forms

characteristic of tetanus bacilli. If such organisms were seen, pure cultures were obtained and mice injected with pure cultures alone and with a protective dose of antitetanus serum. In order to be certain that tetanus bacilli were present it was found to be necessary always to employ pure cultures in the animal experiment tests, since it was found that spasms and death did not always occur after the injection of mixed cultures, even when true tetanus bacilli were present. It is evident, therefore, that there are organisms which interfere with the production of, or destroy, tetanus toxin, and the injection of mixed cultures is not a reliable method to use in the detection of tetanus bacilli. Not only has it been shown that one-third of the male population in the vicinity of Peking carries tetanus bacilli in the intestinal tract, but experiments have shown that the tetanus bacilli multiply in the normal intestine. Thus patients fed for several days with sterilized food continued to pass tetanus bacilli in their stools in very great numbers. Even on such a diet one individual may eliminate several million spores of tetanus bacilli in a single stool. Man thus plays a large part in the distribution of this bacillus in China, where, because of the primitive sanitary arrangements, constant reinfection must take place. Perhaps not so high a percentage of tetanus carriers would be found in similar tests on Western races, which do not live in such intimate contact with the soil, but the fact that this virulent organism is present and multiplies in the normal intestine is of great epidemiological importance.

328. The Action of Carbonic Acid on Gastric Motility.

IN seeking to explain the therapeutic effect of sodium bicarbonate and of those mineral waters—such as Vichy—which contain bicarbonates on the digestive functions; P. CANNOR and W. KOSKOWSKI (*C. R. Soc. Biologie*, 1922, July 22nd, p. 613) have studied the action of carbon dioxide alone on gastric motility. Working with dogs, on which a duodenal fistula had been made, they were able to show that the movements of the stomach are greatly increased after the administration of carbonic acid—and this independently of the direct stimulus of the gas on the mucosa, for the same result was obtained after subcutaneous injection of the gas. Control experiments made with air were all negative. The carbon dioxide, when given beneath the skin, appears to stimulate the peripheral nerves, and this stimulus is transmitted to the stomach by the vagus. Its effect is counteracted by the subsequent injection of atropine. Turning to human beings, they confirmed this action of carbonic acid by following the movements of the stomach under the x-ray screen. Baryta water was given by the mouth, while the CO₂ was sometimes introduced directly into the stomach, sometimes beneath the skin. In each case the contractions were increased greatly and the evacuation of the stomach was hastened in comparison with control cases.

329. Vaccination against Tuberculous Infection.

SOME fresh experiments on the immunization of small animals against tuberculosis are recorded by A. CALMETTE, L. NÉGRE, and A. BOQUET (*Ann. de l'Inst. Pasteur*, September, 1922, p. 625). Rabbits were injected intravenously with either 20 or 30 mg. of a culture of an avirulent strain of the bovine bacillus, or glycerin-bile-potato medium emulsified in saline. Either thirty-five or seventy days later they were tested for immunity by the intravenous administration of 0.01 mg. of a virulent strain of bovine tubercle. Control animals, given the same dose, died within fifty-eight to seventy-five days with lesions of generalized tuberculosis. Of the vaccinated animals, some unfortunately were carried off by an intercurrent infection with an organism of the Pasteurella group, but of the remainder not one developed a generalized tuberculosis, while many survived for several months. A study of the antibody development in the case of vaccinated rabbits showed that the maximum number of units was present about five to six weeks after inoculation, after which they diminished till, in three months, they had disappeared completely from the blood. That the antibody titre and the resistance of the animal to infection did not correspond to each other was shown by the fact that vaccinated rabbits responded in the same way to infection whether tested one month or three months after prophylactic inoculation. Similar experiments conducted on guinea-pigs showed that vaccination by appropriate doses was able to confer a considerable amount of protection against experimental infection. Both with rabbits and guinea-pigs, however, this protection is temporary and does not last more than five to six months. It disappears when all the bacilli given in the vaccine have been absorbed or eliminated and when the power of the animals to react to tuberculin has been lost.

INSULIN AND DIABETES.

A GENERAL STATEMENT OF THE PHYSIOLOGICAL AND THERAPEUTIC EFFECTS OF INSULIN.

BY

J. J. R. MACLEOD, M.B., CH.B. ABERD.,
PROFESSOR OF PHYSIOLOGY, TORONTO UNIVERSITY.

Early Investigations.

LÉPINE¹ was the first to suggest that the condition of diabetes which von Mering and Minkowski² had discovered to follow pancreatectomy might be due to the withdrawal of an internal secretion necessary in the normal animal for the complete metabolism of sugar. The subsequent discoveries that extracts of certain ductless glands, such as the adrenals, have marked pharmacological actions, and that administration of extracts of others, such as the thyroid, can relieve the symptoms which are associated with atrophy of that gland, gave indirect support for the view that the pancreas must also yield an internal secretion. This view was also greatly strengthened by the results of experiments in which it could be clearly demonstrated that a subcutaneous graft of pancreatic tissue is capable of preventing diabetes when the remainder of the pancreas is removed. Many attempts were made to obtain direct proof of the presence of this hormone; thus diabetic animals were given extracts of pancreas prepared in various ways, or blood from the pancreatic veins of normal animals was injected into them, but with no definite benefit. The extracts prepared by Starling and Krowitz,³ by Murlin and Kramer,⁴ by Kleiner,⁵ and by E. L. Scott⁶—to mention only a few of the investigators—did not yield results that were considered by these authors to be sufficiently positive to justify an immediate further development of their investigations with a view to using the extracts in the treatment of diabetes in man. The hope that, in spite of these more or less unsatisfactory results, a method would some day be discovered for the preparation of a pancreatic extract capable of alleviating the symptoms of diabetes was sustained by the publication from time to time of researches the results of which could be interpreted only by assuming the presence of a pancreatic hormone. Among the most striking of these investigations may be mentioned those of Clarke,⁷ who discovered that the isolated mammalian heart—kept alive by perfusing its blood vessels with Locke's solution containing glucose—removes sugar from the perfusion fluid much more rapidly when the fluid used had first of all been perfused through the blood vessels of the pancreas than from fresh Locke's solution. In the light of these researches the majority of investigators concluded that a pancreatic hormone must exist, but that it was impossible to detect its presence in pancreatic extracts because of its destruction by the trypsin and other proteolytic enzymes also present in them.

Starting-point of the Recent Advance.

The problem therefore was to circumvent these enzymes, and to Dr. F. G. Banting is due the credit of suggesting that this might be accomplished by taking advantage of the well-known fact that the cells which secrete the digestive enzymes become completely degenerated in some weeks after ligation of the pancreatic ducts, whereas those of the isles of Langerhans, which apparently secrete the antidiabetic hormone, remain more or less intact. He undertook to see whether extracts of the degenerated gland might yield more certain results, and facilities and assistance were afforded him in my department to put this suggestion to the test of experiment. In collaboration with C. H. Best, Banting observed the effects produced by injection of the extracts on the percentage of sugar in the blood, as well as on the total sugar excretion in the 24-hour urine of dogs, rendered diabetic by extirpation of the pancreas.⁸ From practically the very start of the observations a definite lowering of both of these values was observed to occur. The observations were frequently repeated with all necessary controls, and it was further noted that the exhibition of the extract also greatly improved the subjective condition of the animal and markedly prolonged its life. An untreated depancreatized dog seldom lives beyond three weeks—or four at the outside—whereas with the extracts one such animal lived in excellent condition for ten weeks, when it was killed by chloroform. No trace of pancreas could be seen by the naked eye *post mortem*, though a very small nodule of zymogenous cells was found in the walls of the duodenum in a careful microscopic examination.

First Therapeutic Application.

Having shown by these experiments that the pancreas does contain an antidiabetic hormone the next step was to find a method by which an extract containing it could be made from undegenerated gland. Knowing that proteolytic enzymes are almost, if not entirely, absent in the foetal pancreas (Ibrahim), Banting and Best⁹ prepared extracts from this source, and, finding them also to contain the antidiabetic hormone, then proceeded to try whether an active extract could be prepared from the pancreas of the full-grown ox, by using alcohol as the extracting medium so as to circumvent the destructive action of trypsin, as had previously been suggested by E. L. Scott. Satisfactory results were obtained, and it was considered that the time had now arrived to warrant the administration of the extract to a diabetic patient. This was done in the case of a boy of 14 years suffering from the usual severe type that is so common at this age. The percentage of blood sugar was reduced by about 25 per cent. This may be considered to mark the close of the first and fundamental step in the discovery of insulin, the name which, following Sir E. A. Schaffer's suggestion, has been given to the internal secretion of the pancreas.

Preparation of Insulin.

The presence of a hormone capable of alleviating the symptoms of diabetes both in laboratory animals and in man having been definitely established, it remained to devise suitable methods for the preparation in quantity of an extract containing it and to investigate thoroughly the extent and nature of its physiological and therapeutic actions.

Since the extract used by Banting and Best in the clinical observation referred to was found to cause a certain degree of local irritation, it was necessary, before further clinical trials could be undertaken, to prepare it in purer form. This was successfully accomplished by Dr. J. B. Collip by a method of fractional precipitation with alcohol, the principle of which is described elsewhere,¹⁰ and which in all essential details is the one now used for the preparation of insulin in larger quantity. At this stage of the work it also became necessary to find some simple, readily available laboratory method for testing the potency of the preparations of insulin. Without some method of physiological assay it would have been extremely difficult to develop a satisfactory method of preparation on a large scale, because the potency of each precipitate and filtrate in the process of fractional precipitation of the crude extracts had to be tested before the next step in the preparation was taken.

Pharmacological Assay.

Moreover, a method of pharmacological dosage had to be devised to serve as a guide for the clinical dosage. These requirements were met by the discovery that insulin lowers the percentage of blood sugar in normal rabbits.¹¹ The rate of development, as well as the degree of this hypoglycaemia, depends somewhat on the method of injection (whether subcutaneous or intravenous), on the state of nutrition of the animal, and, of course, on the body weight; but we have found it satisfactory to consider as one unit the amount of insulin which, on subcutaneous injection, can lower the percentage of blood sugar to 0.045 within four hours in a rabbit weighing about 2 kg. from which food has been withheld for sixteen to twenty-four hours. The final solutions of insulin prepared in the University for clinical use are usually concentrated, so that 1 c.cm. contains one unit. The reason why 0.045 was chosen as the percentage to which the sugar should become lowered is that at this level, almost without fail, the animal develops highly characteristic symptoms consisting of violent convulsive seizures with intervals of coma. These symptoms finally terminate in death, but if the animal be injected subcutaneously with dextrose (gram per kilogram) it immediately recovers and usually remains without further symptoms; occasionally a relapse may occur, which, however, can again readily be antidoted by dextrose. No other sugar has the same effect, although a temporary alleviation of the symptoms has sometimes been observed after injections of galactose and lactulose.

Associated Effects of Insulin.

These discoveries, to which Dr. Collip contributed much, opened the way to more extended physiological and clinical investigations. E. C. Noble, J. Hepburn, and J. K. Litchford joined in the physiological investigations, and by excellent team work it was possible in a comparatively short time to

emonstrate many other effects of insulin, a few of which may be briefly alluded to here because of their importance in showing the fundamental nature of its action.

The first step was to extend the investigations of Banting and Best on depancreatized dogs so as to include observations of the respiratory quotient, and the urinary excretion of acetone bodies.¹¹ The former of these is a ratio expressing the relationships of the amount of CO_2 excreted and of O_2 retained by the animal, and it is a reliable qualitative index of the type of metabolism, being of the value of about 1 when carbohydrates are the chief foodstuff undergoing metabolism, 0.7 for fats, and 0.8 for proteins. When diabetes is of the severest type, as in dogs after the removal of the pancreas, the quotient often falls below 0.7, and it is not raised to any significant degree when carbohydrate foods are given. This was found to be the case in the depancreatized dogs used in these investigations, but when insulin was given along with the sugar the quotient immediately rose decidedly, indicating that the power to metabolize carbohydrate had been restored.

Effect on Excretion of Acetone Bodies.

The excretion of acetone bodies in a diabetic dog is not relatively so large as in severe cases of diabetes in man, and it is somewhat irregular. When insulin was given, however, the acetone bodies entirely disappeared from the urine and remained absent so long as the administration was maintained.

Effect on Fat Metabolism.

Very significant results were obtained by comparison of the percentage amounts of glycogen and of fat in the liver and heart in untreated and insulin-treated diabetic animals.¹¹ When no insulin was given the glycogen content of the liver was found to be very low—not more than 1 per cent.—whereas that in the heart was decidedly above the normal; after insulin (and sugar) the percentage of glycogen in the liver rose to the exceptionally high value of over 12 per cent., and there was a decided fall in the percentage in the heart. The fat content of the liver fell from about 12 per cent. in untreated animals to below 5 in those treated for two days with insulin, and there was also a decided diminution in the fat content of the blood. These observations indicate that insulin, possibly because of its influence primarily on carbohydrate metabolism, also affects that of fat.

Influence on Carbohydrate Metabolism.

In the long series of chemical processes which enter into the metabolism of the carbohydrates there are only two products which are sufficiently stable to permit of quantitative determination: these are the sugar of the blood and the glycogen of the liver. In diabetes the former increases and the latter decreases, and insulin restores them to, or beyond, their normal levels. Taking this along with the fact that oxidation of the glucose molecule, as revealed by the respiratory quotient, fails to occur in diabetes, but does occur, as in a normal animal, when insulin is given, it is evident that this hormone must be an essential factor in the regulation of carbohydrate metabolism. Not only, however, does insulin remove the symptoms of diabetes due to absence of insulin from the body, but it also prevents the development of the hyperglycaemia, and presumably of the glycosuria, which can be induced by other experimental means.¹² The best known of these are puncture of the floor of the fourth ventricle of the medulla, subcutaneous injections of epinephrin, and the various forms of asphyxia, including ether anaesthesia. In rabbits previously fed abundantly with carbohydrate rich foods so as to ensure a high percentage of glycogen in the liver, none of these experimental procedures was found to cause more than a slight increase in the blood sugar in animals previously injected with insulin. The only one of them which could cause any decided degree of hypoglycaemia after insulin was that due to excessive doses of epinephrin, and it is possible that a method for the precise dosage of insulin based on its power to antidote known quantities of epinephrin may be evolved. That insulin almost entirely prevents the development of hyperglycaemia in ether anaesthesia has an evident practical application in surgical practice.

Effect on Cardiac Nutrition.

As to the mechanism of the action of insulin we are as yet in the dark. One other fact of great importance may, however, be mentioned—namely, that it increases the rate of

sugar consumption by the isolated mammalian heart.¹⁴ These observations were made on the hearts of rabbits. Immediately after killing the animal the heart was excised and perfused through the aorta with Leck's solution containing about 0.2 per cent. of glucose. From time to time samples of this fluid were removed for determination of the percentage of reducing power. When no insulin was added to the perfusion fluid the average rate of disappearance of sugar was 0.8 mg. per gram of heart per hour; when insulin was added to the fluid the average was over 3 mg. It was not possible to determine whether the more rapid disappearance of sugar under insulin was due to its increased combustion or to its being deposited as glycogen in the heart. This it will be possible to determine only by observing the respiratory quotient in a heart-lung preparation, such as has been used by Starling and his collaborators.

Mode of Action of Insulin.

This observation on the heart would seem to narrow down the locus of action of insulin to the muscular tissue, and we therefore hoped to find that we could demonstrate that addition of insulin would accelerate the rate of disappearance of glucose from incubated (Buehner) extracts of muscle. So far, however, the results have been entirely negative, although with Dr. G. S. Eadie's assistance we have repeated them in various modifications of the experimental conditions. Neither does insulin have an influence on the rate of disappearance of glucose from drawn blood (glycolysis), nor on the rate at which glycogen is broken down in incubated pieces of liver. The object of doing these experiments is not only that some light might be thrown on the mechanism of action of insulin, but also that some *in vitro* method might be discovered for measurement of the potency of insulin.

Insulin in Diabetes Mellitus.

The effects of insulin in removing the cardinal symptoms of diabetes in depancreatized dogs, as well as those observed on normal rabbits, have been found also to follow its administration in the disease, diabetes mellitus, in man. Every detail of the therapeutic effects of this hormone was definitely forecasted by animal experimentation—the effect on the blood sugar and on the urinary sugar, the diminution of acetone bodies (to which the incidence of fatal coma is related), the prolongation of life, the raising of the power to metabolize sugar—and it was not until this had been established beyond doubt in the laboratory that insulin was given in the wards. Without the experimental demonstration of its effects no physician would have been justified in attempting the therapeutic investigation of insulin. Had he attempted to do so unaided by the results of observations on rabbits, it is almost certain that sooner or later an overdose would have been given, causing convulsions (not unlike those of diabetic coma itself) for which there would have been no indication as to what remedy should be used. The experiments on rabbits, however, showed clearly that these alarming symptoms are immediately antidoted by injection of glucose, and it is of interest that in one or two patients in whom there have been premonitory indications of their possible occurrence exhibition of glucose has immediately and permanently removed them.

A preliminary paper on the principal clinical effects was published in March by Banting, Best, Collip, Campbell, and Fletcher,¹⁵ and since that date a sufficient number of cases of all degrees of the disease have now been observed—partly in the clinic of Dr. Banting at the Christie Street Hospital of the Soldiers' Civil Re-establishment in Toronto, partly in the clinic of Professor Duncan Graham in the Toronto General Hospital, and partly in certain diabetic clinics in the United States—to justify the statement that when insulin is administered subcutaneously in adequate dosage it is capable, within a remarkably short time, of removing the cardinal symptoms of the disease for a period of several hours. To suppress the symptoms permanently, however, the injections must be repeated, the practice at present being twice daily. So long as the administration is maintained the patient is able to assimilate much more carbohydrate than previously, and he gains weight and with it both physical and mental vigour, so that the despondency and apathy that are so prominent in these cases disappear. Whether the diabetic condition is in any degree cured by the rest which is given to the damaged pancreatic function by insulin cannot as yet be stated. It is perhaps in the adolescent forms of the disease that these results have been most marked, but there

can be no doubt that when insulin comes to be more available its exhibition along with intelligent control of diet will have the same beneficial results in all the serious forms of the disease. In cases of threatened coma its value is undoubted, and this is also the case when it is used as a precautionary measure against post-operative risk in surgical practice.

Until the clinical effects have been more thoroughly investigated it would be out of place here to discuss in further detail the therapeutic value of insulin.

Preparation on the Large Scale.

It remains to explain the steps that have been taken by the University of Toronto to safeguard the production, standardization and distribution of insulin. Realizing that the publication of the method of its preparation might be followed by an uncontrolled commercial exploitation of insulin, with the consequent of its improper use in general practice, the chief originators of the method generously offered to apply for patents covering its production, and to hand these over to the University provided this body would assume the function of licensing approved manufacturers to produce and sell it at a reasonable cost. Patents have therefore been applied for in Canada, the United States, Great Britain, and other countries, and the University has appointed a committee, composed partly of those who have participated in the investigations and partly of members of the Board of Governors, to advise it with regard to the conditions under which licences should be granted.

As a first step this committee recommended that licences should not be freely granted until every possible detail of the manufacture on a large scale of a preparation of known and constant potency had been thoroughly worked out. This step was taken because of the unexpected difficulties which were encountered when large scale production was attempted in the Connaught Antitoxin Laboratories of the University. It was found that whereas non-irritating preparations of insulin of constant potency could readily be obtained by Collip's procedure in the laboratory, the yields were for some time extremely unsatisfactory when a large scale production was attempted.

Protection from Commercial Exploitation.

After these difficulties had been overcome it was decided still further to expand the production by collaborating with some firm engaged in the manufacture of extracts from slaughterhouse materials. This was done under a special agreement by which the University undertook not to issue licences to other firms until the lapse of a period during which the large scale method could be carried out so as to yield the maximal output of preparation of standard and uniform potency both when assayed by the rabbit test and when tested therapeutically on diabetic patients. For the clinical assays this firm agreed to distribute a sufficient number of free samples of their preparation to various physicians specializing in the treatment of diabetes in properly controlled clinics. This collaboration between the committee of the University and a firm in the United States is proceeding at the present time, and the physicians receiving insulin are reporting their experiences as to its potency and value. Whenever it is certain that a thoroughly reliable large scale method for a product of constant potency has been worked out the special agreement between the University and the collaborating firm will terminate, and the University will issue licences to other approved firms.

Realizing that it could not exercise proper supervision over the production of insulin in more countries than Canada and the United States, the University has offered to the Medical Research Council the assignment of the patents applied for in Great Britain for the purpose of safeguarding the production and standardization of insulin in that country.

Remarks

ON THE

SURGERY OF THE PITUITARY GLAND.*

BY

A. J. WALTON, M.S., F.R.C.S.,

SURGEON, LONDON HOSPITAL.

[With Special Plate.]

EVEN in adult life the two portions of the pituitary gland remain distinct, and each appears to have a very different function. Their somewhat complicated development will therefore have to be briefly considered before discussing the manifestations of disease of the gland.

DEVELOPMENT.

In the adult the pituitary gland forms a small oval structure, which is somewhat flattened from above downwards, and fills the pituitary fossa of the sphenoid bone. Its longest diameter, which usually lies transversely, is about half an inch. On section it can be seen to be distinctly formed of two parts, an anterior and a posterior. The anterior portion, often described as the epithelial or glandular part, is in man considerably the larger, and forms about two-thirds of the total gland. It is immediately in front of, and in part envelops, the posterior lobe, which may be regarded as being embedded in its posterior surface. Blair Bell has shown that this position is largely dependent upon the shape of the fossa, for in animals with a deep fossa, such as the cat, the pars nervosa lies posteriorly; while in dogs, which have a shallow fossa, it is placed superior to the glandular part. The glandular portion is developed from the stomodaeum at a very early age from a recess, known as Rathke's pouch, which grows upwards from the junction of the pharyngeal membrane with the roof of the primitive stomodaeum, and which, according to Bell, may be visible even in a foetus of 2.5 mm. Such a method of development is remarkably constant within the vertebrate series, and may be found in some form even as far back as the Cyclostomata. The pouch so formed passes upwards in front of the notochord and between the trabeculae cranii to the base of the brain. The neck of the sac becomes constricted, but the upper portion dilates to form what is known as the pituitary sac. Later, as the sphenoid develops, the stalk becomes constricted and disappears, so that the pituitary sac is entirely shut off from the stomodaeum. The position of this stalk is usually regarded as lying between the pre-sphenoid and post-sphenoid, but Cope has shown that it traverses the anterior part of the post-sphenoid. Although the stalk by these means is as a rule entirely destroyed, Duffy has shown that certain squamous-celled tumours which arise in or about the pituitary probably originate in the remnants of this stalk, which may persist in the post-sphenoid or beneath the capsule of the anterior lobe. Erdheim has reported a case of acromegaly in which a tumour formed of cells resembling those of the anterior lobe was imprisoned in the posterior part of the sphenoid. The pituitary sac thus cut off from the primitive pharynx undergoes very considerable proliferation. It becomes more or less triadial in outline, and later gives off a large number of diverticula, so that it comes to have a glandular appearance.

The fully developed anterior lobe comes therefore to be composed of well-defined epithelial cells supported by a framework of fine connective tissue and showing large blood vessels and sinuses. Not uncommonly the cells are arranged in the form of small vesicles containing a granular-like material somewhat resembling colloid. The work of Bell and Cushing, among others, shows that there is a very great variation in the appearance of this portion of the gland in different physiological and pathological states. It can always be determined, however, that there are two main types of cells: one of these stains well and is spoken of as the chromophil cell, which may be either basophil or acidophil; the other stains poorly, and is spoken of as the neutrophil or chromophobe cell.

The anterior lobe appears to become larger and more active in certain conditions—such as during pregnancy, after

* An abstract of this paper was presented to the Section of Surgery at the Annual Meeting of the British Medical Association at Glasgow.

thyroidectomy, and after castration. It is also always larger in adult parous females than in men or nulliparae.

The posterior part, or pars nervosa, has an entirely different origin. Shortly after the appearance of Rathke's pouch a depression is seen in the floor of the forebrain. As development proceeds this pouch dilates while its stalk becomes constricted. The dilated portion comes into close relationship with the posterior surface of the anterior lobe and is in part enveloped by it. As it grows its wall becomes thickened, and as a rule the cavity entirely disappears, but occasionally a small part may remain as a minute vesicle which is still lined by ciliated columnar epithelium. The stalk, unlike that of the anterior lobe, does not disappear but persists as the infundibulum or stalk of the pituitary gland. This is attached above to the anterior part of the tuber cinereum, which is a thin layer of gray matter alone separating the pituitary fossa from the cavity of the third ventricle. Indeed, a small pouch of the third ventricle is continued downwards into the upper part of the infundibulum. In adult life this portion of the gland is seen to consist of cells and fibres which are apparently neuroglial in character. Occasionally large cells, apparently from the pars intermedia, may be seen in the substance of the pars nervosa, and generally there can be distinguished a peculiar brown pigment.

It has been shown that as the anterior lobe develops the original pituitary sac throws out buds which by irregular growth form the glandular-like anterior lobe of the pituitary. The posterior wall of the sac remains, however, simple and comes to lie in close relationship with the infundibulum of the posterior lobe, while the pituitary sac itself persists as a narrow cleft which appears to separate the anterior from the posterior lobe. This thin posterior wall of the sac remains epithelial in character and is usually spoken of as juxtaneural epithelium. This portion forms in the adult the pars intermedia. It is developmentally a portion of the anterior lobe, and it and the anterior lobe are generally spoken of together as the hypophysis. Like the rest of the gland, it varies very considerably in its size and extent in different animals. In man the epithelium is very scanty, and only forms a thin layer over the pars nervosa, where it adjoins the narrow cleft. The cells are faintly granular and either neutrophil or slightly basophil. A colloid-like secretion is sometimes found in this part and also in the cleft. Whereas the anterior lobe has a very fair blood supply from the internal carotid arteries, the pars intermedia appears to contain no blood vessels or lymphatics.

ANATOMY.

The anatomical relations of the gland are of extreme importance surgically, and it is owing to the inaccessibility of the fossa and to the importance of the surrounding structures that surgical measures have been so limited in the past.

The gland itself lies in a deep hollowed-out fossa in the sphenoid bone, and therefore lies in the centre of the base of the cranium and almost equidistant from the roof of the nose and the posterior margin of the foramen magnum. The shape of the fossa varies considerably. Copo has shown that the antero-posterior measurement is from 7 to 14 mm., the transverse from 9 to 15 mm., and the depth from 3 to 10 mm. Immediately beneath it the basiphosphoid is hollowed out by the presence of the sphenoidal sinus, but both the size of the pituitary fossa and the size of the sphenoidal sinus are subject to very considerable variation. Gibson, who took careful tracings of 107 skulls, found that the sphenoidal sinus was completely absent in 3 per cent., very small in 9 per cent., and was separated from the sella turcica by a thick anterior wall in 9 per cent. What is perhaps of more importance surgically is that he was able to show that the sinus did not project below the sella turcica in 22 per cent. of the cases. The sphenoidal sinus not infrequently shows an intersphenoidal septum which is variable in its position, and may be so much to one side that if taken for a guide in an intranasal operation it may lead to one of the cavernous sinuses being opened in mistake for the pituitary fossa. The floor of the sphenoidal sinus is formed laterally by the cornua sphenoidalia and medially by the ethmoidal spine, to which is attached the vomer bone. It will thus be seen that any approach to the pituitary fossa by the intranasal route, which is the operation of choice, is not only associated with considerable difficulties owing to the variations in the anatomical conditions, but, the opening being small, it is impossible to remove completely any of the larger tumours in this position.

The bony floor of the fossa is slightly concave and is limited laterally by a slight ridge of bone which separates it from the carotid groove. Posteriorly the cavity is overhung by the dorsum sellae, which separates it from the pons Varolii and the basilar artery. The upper portion of this ridge projects on either side and overhangs the pituitary fossa to form the two posterior clinoid processes. Anteriorly the fossa is limited by a transverso ridge of bone, the olivary eminence or tuberculum sellae, which is often continued outwards laterally into two small spurs of bone—the middle clinoid processes. These middle clinoid processes limit posteriorly the groove for the carotid artery where it turns upwards from the cavernous sinus. Sometimes the middle clinoid processes may be sufficiently long to join with the anterior clinoid process and thus convert the carotid groove into a canal. In front of the olivary eminence is the optic groove, which terminates on either side in the optic chiasma. The pituitary fossa thus formed is lined by a layer of dura mater and is covered in above by a fold of the same structure, which is the diaphragma sellae. This is complete except for a small opening in the centre through which passes the infundibulum.

The pituitary, therefore, lies in a closed box, which anteriorly, posteriorly, and inferiorly is formed of bone, and above and on both sides is formed of dura mater. Each lateral wall is separated to enclose the cavernous sinus containing the carotid artery, the third, fourth, sixth, and branches of the fifth nerves. Just external to the third division of the fifth nerve is the middle meningeal artery. These lateral relationships of the pituitary are of considerable importance and make an approach to the gland by the temporal route a difficult and dangerous procedure. To obtain adequate access by this route it would be necessary to lift up the temporal lobe and with it the optic tract, and to open the diaphragma sellae above and internal to the cavernous sinus. Separating the structures of the interpeduncular space from the base of the skull and the pituitary fossa is a large subarachnoid space, the cisterna basalis, through which passes the infundibulum. Anteriorly the fossa is in part shut in by the anterior clinoid processes and the olivary eminence, and it is said that sometimes they may project so far over the pituitary fossa as to make approach by the anterior or frontal route difficult. In practice, however, this is found not to be the case, for by lifting up the frontal lobe it is always possible to reach to the bottom of the pituitary fossa.

Running transversely across the front of the gland in the optic chiasma and at a somewhat higher level is the anterior communicating artery. Antero-laterally are the carotid arteries turning forwards and the optic tracts. Although the optic chiasma lies close to the bone it will nearly always be found that a tumour of the pituitary elevates the chiasma from the bone, and presents in the triangular space between the two optic nerves. Thus it often happens that at operation, although a tumour the size of a walnut is readily removed and the floor of the pituitary fossa freely exposed, yet the optic chiasma has been pushed so far upwards and backwards that it is not seen in the operating field.

The arterial relationships to the gland are of considerable importance. Posterior to the dorsum sellae runs the basilar artery, which divides superiorly to form the two posterior cerebral arteries. Running forwards from these arteries close to their origin and encircling the infundibulum are the two posterior communicating arteries, which join the internal carotid arteries almost immediately after they have appeared above the middle clinoid process. They thus lie upon the diaphragma sellae and the superior surface of the pituitary gland. The two internal carotids pass upwards and give off the anterior cerebral arteries, which are united by the anterior communicating artery. It will thus be seen that the posterior communicating arteries run beneath the optic tracts, whereas the internal carotid and the anterior cerebral arteries run external and superior to the optic nerves. Hence a pituitary tumour, pushing upwards the optic chiasma, will compress the optic nerves between itself and the anterior ring formed by the circle of Willis. We therefore have an explanation as to why it is that sometimes a pituitary tumour will give only a bitemporal hemianopsia and sometimes will lead to complete optic atrophy and blindness.

FUNCTIONS.

That the internal secretions of the pituitary gland have a very important bearing upon the general metabolism has been known for a considerable period, but accurate knowledge has

been almost wholly developed since Mario's observations in 1888 upon the changes in the gland that were found associated with acromegaly. This knowledge is in part based upon observations of the effects of administered extracts of pituitary, partly upon experimental operations upon animals, and partly upon observations of the changes found in certain physiological and pathological states. At one time it appeared as though the whole of the patient's appearance and character might depend upon slight changes in this small gland. More recent work makes it evident, however, that there is a very real interrelationship between this and other glands in the body, for under certain circumstances the whole of the gland may be removed and only beneficial effects will result.

A study of the internal secretion of this gland is associated with peculiar difficulties, for not only do the anterior and posterior parts appear to have entirely different functions, but the effects will differ according to whether the changes occurred before or after puberty. There is still, therefore, some uncertainty as to what are the parts played by the individual portions of the gland, for both experimentally and clinically it is difficult to obtain a lesion which is limited to one or other lobe. There even seems to be a certain amount of doubt as to what is the effect of complete extirpation of the gland. The evidence produced by Cushing would seem to show that complete destruction of the gland is incompatible with life, but Sir Victor Horsley brought forward a considerable amount of evidence to show that an animal could survive this operation. My own experience is very definite. I have two cases in which the gland has been completely extirpated; the pituitary fossa at operation was left absolutely bare and lined with smooth dura. Both these cases have survived and have made very good progress. It would appear, therefore, quite certain that the function of the gland can be almost wholly undertaken by other glands in the body.

The Anterior Lobe.

Since Pierre Marie first pointed out that cases of acromegaly were always associated with changes in the pituitary gland a large amount of evidence has accumulated to make it perfectly definite that this portion controls the metabolism and growth of the skeleton, including the bones, cartilage, and connective tissues. If there is an increase in the internal secretion before growth is completed the patient will develop into a giant. There will be a very great overgrowth of the bony skeleton, which, however, is rarely if ever symmetrical, and the patients will generally show not only structural weakness but many of the irregular outgrowths which are found in all cases of acromegaly. Should the oversecretion be delayed until adult life then there will be an irregular overgrowth of the bony and connective tissue, giving rise to that curious syndrome known as acromegaly. In addition to these clearly defined effects upon the skeletal tissues it is probable that an overgrowth of the gland is associated with changes in the sexual glands, for most cases of acromegaly are clearly asexual. It is possible also that the anterior lobe may to a certain extent control the deposit of fat.

Pars Intermedia.

It is very difficult, if not impossible, to distinguish the functions of this portion from those of the posterior lobe, but Evans holds the view that the pars intermedia produces a colloid-like material which affects the blood pressure and the urinary secretion. It may lower or raise the blood pressure and may increase or decrease the secretion of urine. It is held by many observers that all the effects which are described as due to changes in the posterior lobe are really due to changes in the pars intermedia, for it is difficult to see what secretion, if any, could be formed from the posterior lobe, which is apparently made up of neuroglia alone.

The Posterior Lobe.

It is a curious fact that whereas the functions of the anterior lobe are shown clinically to be so distinct, those of the posterior lobe are less well defined, yet extracts are much more easily prepared from the posterior, probably with the pars intermedia, and have a very definite effect. So far no demonstrable changes have been seen to follow the administration of extracts of the anterior lobe, although Goetsch has claimed that the administration of such extracts leads in young animals to an increase in the rate

of growth and early sexual development. The effects of extracts of the posterior lobe are many, and may be grouped as follows:

1. *A Pressor Effect.*—Howell in 1898 first showed clearly that it was the posterior lobe extracts alone which gave pressor effects. This has since been confirmed by many observers, who show that this pressor effect is due to a slowing and increase in force of the heart's action. Second and subsequent injections given soon after the first have little or no effect until the first has all been destroyed or excreted by the organism. The effect is maintained for a much longer period than that obtained by suprarenal extract.

2. *A Depressor Effect.*—It has been noted by many observers that an injection of this portion of the gland may lead not to a rise but to a fall in the blood pressure. Schafer and Vincent noticed that this fall followed second and subsequent doses if they were given soon after the first. Others have noticed that such a depressor effect followed shortly after the pressor effect had died away. Blair Bell, on the other hand, has shown that there is a preliminary fall before the blood pressure rises. It is this uncertainty as to the relationships between the pressor and depressor effects that has made the use of this drug in the treatment of surgical shock not entirely free from danger.

3. *A Diuretic Effect.*—Magnus and Schafer first showed that injections of posterior lobe extract had a diuretic effect. With this they observed that the arteries of the kidney were dilated, whereas the arteries of the rest of the body were constricted. The diuretic effect was not, however, simply a vascular phenomenon, for later Schafer and Herring showed that it was present even when general vaso-constriction was absent. Herring also showed that this effect was produced entirely by the pars nervosa and not by the whole posterior lobe. It is not, therefore, as has sometimes been thought, due to pressure upon the fourth ventricle.

4. *A Galactagogue Effect.*—The use of extract of the posterior lobe has come into considerable favour for its value in increasing the flow of milk in lactating women. Blair Bell points out that the effect is so rapid that it would seem improbable that it is due to the active principle being excreted by the gland and so stimulating the cells. It is an interesting point, however, that the increased flow is only of short duration and that the daily flow does not seem to be increased in amount. The increased flow shows a slight increase in the amount of fat, but is otherwise normal. The later excretion, however, shows a slight diminution in the amount of fat, so that the total excretion, like the total quantity, is not increased. Blair Bell holds the view that the increase in the rate of expulsion is simply due to the effect upon the muscular fibres, so that there is in reality an increased excretion rather than an increased flow.

5. *A Stimulative Effect upon Unstriated Muscle.*—One of the most valuable effects of pituitary extract is its power of causing rapid and powerful contraction of unstriated muscle. Bell has shown clearly that although the extract has no effect upon the resting uterine muscle it causes powerful contraction of the uterus in menstruating and pregnant animals. It has thus been largely used in gynaecological work. Similar powerful effects have been found in the case of the intestinal muscles, and the drug is now very largely used in many forms of ileus. A similar effect is seen upon the muscular wall of the bladder.

6. *Effects upon Carbohydrate Tolerance.*—Many diseases of the pituitary gland are associated with a very distinct and definite change in the patient's tolerance to carbohydrate, so that not infrequently there has been noticed the presence of glycosuria. There is some doubt as to which portion of the gland is responsible for this effect. It may be said to have been definitely established that with lesions such as acromegaly there is a diminution in the tolerance to carbohydrates. One of my own patients, who was a clear case of this disease, had a marked glycosuria. Lesions of the posterior lobe, on the other hand, show as a rule an increased tolerance, but it is not possible to say definitely whether the effect is due to over- or under-secretion. It might be possible that in acromegaly the glycosuria is due to overaction of the anterior lobe or due to underaction of the posterior lobe owing to the pressure of the enlarged anterior part.

PATHOLOGY.

In some of the cases in which the clinical symptoms clearly indicate that there is a diminution in the secretion of

the pituitary a skiagram may show that this fossa is smaller than normal. Few, if any, of these cases have had the pituitary examined, but the smallness of the fossa and the absence of local pressure symptoms would indicate that the symptoms are due to a simple atrophy of the gland. In the majority, however, the pituitary fossa is much enlarged, and this is true whether the symptoms are those of increase or decrease. If the symptoms are those of increased secretion there is an overgrowth of the pituitary gland which has a positive function, but where the symptoms point to a diminution of the secretion there may be a tumour such as a fibroma or sarcoma of the pituitary itself, or a neoplasm of the surrounding tissue which has caused local pressure symptoms and widening of the pituitary fossa, but having no internal secretion leads to a destruction of the pituitary with a diminution of its secretion. A similar condition may be found with cysts, and in my own experience the majority of the cases of hypopituitarism are found associated with a cystic change.

Much attention has been given to the nature of the pathological lesions found with an increased secretion. Cope has analysed 64 cases which were published by Cushing, Hirsch, and von Eiselsberg. Of these 64, 45 were adenomata and 7 were cysts. Others have been certified as endotheliomas, mixed tumours, epithelial cancer, sarcomas, etc. It is probable, however, that the majority of these latter were really adenomata. Such tumours are very richly cellular and give a microscopic appearance which is very suggestive of a carcinomatous change. They are, however, quite localized, are not associated with secondaries, and would seem not to recur after complete removal. Frazier has also laid stress upon the great variation in the published reports of the pathology, and in many which are reported as malignant there has been no evidence of recurrence or of secondary deposits after a number of years. Sekiguchi has carried out an interesting investigation in cases that had died of mammary cancer. In two such cases he found that there were secondary deposits in the posterior lobe, and in both cases the patient had polyuria, which he regards as being due to compression of the pars intermedia by pressure of the secondary deposits in the pars posterior. It may be said, then, that the majority of cases that show an increased secretion are due to the presence of functioning adenomata. When there is clinical evidence of a diminished secretion the lesion is most commonly a cyst or a parapituitary tumour, but may occasionally be due to a simple atrophy. The diagnosis of the latter type is simple, for there will be no local pressure symptoms and a skiagram will show a diminution rather than an increase in size of the pituitary fossa.

CLINICAL MANIFESTATIONS.

There are certain diseases in which it is well established that there is a lesion of the pituitary gland, but there are others in which the evidence is much less certain. Cope, for instance, has shown that there is a close relationship between the pituitary and the thyroid, and that a diminution in the thyroid gland may be associated with an overgrowth in the pituitary. He has found that the fossa may be enlarged in cases of cretinism and is often considerably enlarged with achondroplasia. In the well-established cases the pituitary lesion will give rise to symptoms which may be placed in three groups. There are, first, those which are dependent upon some alteration in the secretion, which is either diminished or increased, and according to whether this variation in the secretion occurs in early or adult life so will different symptoms arise. Secondly, there are symptoms due to local pressure of the enlarged pituitary on the surrounding tissue. Lastly, there are a group of symptoms which are due to a general increase of the intracranial pressure.

Disturbances of Internal Secretion.

There are still many points of doubt as to which portion of the gland is actually at fault with individual disease, and not uncommonly curious combinations of symptoms may be found. It is possible, for instance, that an adenoma of the anterior lobe will give rise to an increased secretion in this portion, but at the same time the tumour might cause a pressure atrophy of the posterior lobe and so give rise to symptoms of hypopituitarism. Such a combination of Fröhlich's disease and acromegaly has been reported by Frazier and another by von Eiselsberg. It is therefore not yet possible to say with certainty what symptoms correspond

with different lesions of the gland, but it is probable that the following classification is a correct one:

Classification of Symptoms.

Anterior Lobe:—

- (a) Increase of function: (1) In young patients = gigantism. (2) In adults = acromegaly.
- (b) Decrease of function: (1) In young = ateliosis (Lorain's disease), possibly achondroplasia. (2) In adults doubtful; possibly fragilitas ossium.

Posterior Lobe:—

- (a) Increase of function: Doubtful; possibly some forms of precocious development and some cases of congenitally high blood pressure.
- (b) Decrease of function: (1) In young = dystrophia adiposogenitalis (Fröhlich's disease). (2) In adults = adiposis dolorosa.

Gigantism.

The relationships of gigantism to lesions of the pituitary gland have been well appreciated since Sternberg showed that 20 per cent. of acromegals were giants and 40 per cent. of giants developed acromegaly. Cushing has reported several cases of giants with lesions of the pituitary gland, and it has been realized that a similar change existed in many of the well-known giants. It is also interesting to note that very few of these so-called giants are normally developed. Most of them show an unusual size of the hands and feet, and many of them, although so big, show many of the irregular changes in growth which are associated with acromegaly. For instance, they often have very long arms and legs, irregular overgrowth of the facial bones, and marked kyphosis. Brissaud was the first to point out that acromegaly was probably gigantism of adult life, or that gigantism could be regarded as acromegaly occurring during the period of growth. He also showed that examples of acromegaly and gigantism might be found in the same family.

Acromegaly.

This condition has been so frequently described, and so many cases have been reported since Pierre Marie's first complete description in 1886, that it will suffice to give a very brief account of the clinical condition.

In nearly all cases there is a definite change in the pituitary gland which takes the part of an adenomatous overgrowth. Even in the few cases that have been reported where acromegaly has occurred without any visible change in the gland, it is probable that a microscopic examination would show a definite overgrowth, as in cases reported by von Eiselsberg. As a general rule the disease commences after the age of 30, and males and females appear to be almost equally affected. There is a remarkable similarity in the appearance of all such patients. The face as a whole shows general hypertrophy, especially in the vertical direction. The forehead appears low and narrow, the orbital margins are much enlarged and thickened, and a skiagram will show an increase in size of the frontal sinuses. The temporal areas appear to be depressed. The nose is widened and enlarged. The mouth and throat are large. The lower jaw is large. The inferior maxillary there is a separation of the teeth, so that in time they come to form an arch greater than that of the upper teeth. The jaw itself projects and is enlarged from above downwards. The tongue is hypertrophied and the ears are somewhat thickened and enlarged. The lips are thickened and often appear to be negroid in type. A skiagram will reveal some thickening of the tables of the skull and considerable overgrowth of the orbital margins and jaws. The pituitary fossa is enlarged and the clinoid processes may be eroded. The spine shows a definite kyphosis and some of the patients may have a distinct increase in height. In three of my patients, although adults, the height had increased from one to three inches since the onset of the disease. The thorax is enlarged, widened, and deepened. There is a wide subcostal angle. The pelvis is enlarged in all directions and the bones are generally thickened. Perhaps the most characteristic change is that in the hands and feet. They are generally increased in size, especially in the lateral direction. The patients will often have noticed that since the onset of the disease they have had to take much larger boots and gloves. The thickening consists of all the tissues. At first the soft tissues are enlarged so that the fingers are more or less cylindrical, the hands wider, and the heels thicker. The toes, like the fingers, are cylindrical, and the foot is much wider at the base of the toes. At this stage a skiagram will show no

evidence of any bony change, but later there is a subperiosteal overgrowth, especially of the proximal phalanges. In advanced cases there may be a hypertrophy of the muscles of the arms and legs, which later is replaced by an atrophy, and the x-rays will show a deposit of new bone beneath the periosteum of the long bones. Sexual changes are definite. In women the breasts atrophy and amenorrhoea is an early symptom. The external genitalia are hypertrophied and there is a decrease in sexual desire. The heart is often hypertrophied. The thyroid may be small and the larynx hypertrophied, so that in women the voice becomes deeper and stronger and resembles that of a man. The skin may show profuse sweating and pigmentation, and the hair becomes coarse and wiry. The intelligence is as a rule good, but later, when there is evidence of general pressure, the mental functions may be impaired. The patients will often complain of severe, but ill-defined, pain in the limbs, back, and joints. Local or general pressure symptoms may be present in addition, and it is not uncommon, as in one of my cases, for glycosuria to be present and to require treatment before an operation is undertaken.

Ateliosis, or Lorain's Disease.

This condition may be regarded as the exact reverse of gigantism. The condition generally occurs quite early in life, and thus the patient remains small and stunted, and never arrives at full development. In some interesting cases the condition starts late in life, and then, as in one of my cases, the patient may become smaller and of poorer physique after he has developed along normal lines. This lack of growth is even, so that the proportions of the different parts of the skeleton remain more or less normal, and hence the condition is easily distinguishable from achondroplasia. Several observers, however, have noticed changes in the pituitary in association with achondroplasia. With the lack of growth there is a failure to develop the secondary sexual characteristics, so that the patients appear to be younger than they really are, and at the age of 35 or 40 may seem to be only 14 years of age. The bones are small and relatively fragile, and the muscular attachments are poorly developed. The junction at the epiphysis is greatly delayed, but the formation of the bones is regular, and there is no enlargement of the epiphyseal ends, as may be seen with achondroplasia. The skull is small with thin bones, and a skiagram may show very definite changes in the pituitary fossa, which varies with the nature of the lesion. If, as is not uncommon, there is a simple cyst, the fossa may be much dilated and the clinoid processes may be absorbed. The lower jaw is badly developed and there is a poor eruption of the teeth. The muscles are ill developed and are feminine in character. The skin is also soft, delicate, and white. The body and face remain hairless, and the voice is thin, high, and piping, so that the patient, if a male, retains many of the female characteristics. The intelligence is generally below normal. The appetite is poor, and there may be alterations in the secretion of urine, there being generally polyuria. Glycosuria is not present and as a rule the sugar tolerance seems to be increased. Later, local pressure symptoms, and especially those upon the optic chiasma and nerves, will become evident. Headache and other signs of general pressure will appear as late manifestations.

If the symptoms appear soon after puberty, as in the sixth case of my series, these changes of general atrophy will appear after the patient has reached a normal height, and after operation they will gradually disappear. This progress throws a certain amount of doubt upon the belief that the symptoms are due to a simple hyposecretion of the anterior lobe, for in my own case there was an enormous improvement after the whole of the pituitary had been removed, and the patient is now rapidly passing again into a normal condition, and this in spite of the fact that he has taken no pituitary extract by mouth. Cases of atrophy occurring in late adult life have not been recorded, but the changes that are found in cases of fragilitas ossium would suggest that they might be due to a hyposecretion of the posterior lobe, and it will be of interest to note in the future whether such changes are recorded.

Posterior Lobe Increase.

There is some doubt as to the actual changes which occur with an increase of function of the posterior lobe. One would imagine that this would give rise to a greatly increased blood pressure, polyuria, and a generally active metabolism. Thus theoretically it would seem possible that some of the cases of chronic nephritis in early life would be due to such changes.

On the other hand, certain cases have been reported of children who have rapidly developed, and at the age of 8 or 9 have shown an abnormal development both physically and sexually. Poynton reports a case, for instance, of a boy aged 8 who had a well-marked monstachio, beard, and whiskers. He regarded the case as being due to a pituitary lesion and not to a suprarenal growth. Similar cases of precocious development, both physically and sexually, have been reported in association with pituitary tumours. Such cases have been reported by Howell, Ogilvie, Frank-Hochwart, Heubner, Gutzeit, Marburg, Oestreich and Slawyk. Marburg believes, however, that in the case of a pituitary tumour they are due to hyposecretion, while with a lesion of the pituitary there is a hypersecretion of the posterior lobe.

Dystrophia Adiposa Genitalis (Fröhlich's Disease).

It is of interest to note that many of the cases of this condition have shown the presence of a cyst in the pituitary gland. My own cases are of special interest from this point of view, for the patient who showed Lorain's disease had a large semi-calcareous cyst, which in the x-ray photograph was well forward and showed destruction of the anterior clinoid processes; whereas the girl who had typical Fröhlich's symptoms had also a calcareous tumour, which was shown by the skiagram to be far back and had led to a destruction of the posterior clinoid processes. The changes in the body are remarkably characteristic. There is an enormous overgrowth of the subcutaneous fat, the deposit of which is more or less general, but has a tendency to be placed so as to exaggerate the female outline of figure. Thus, in a male, there is a relatively greater thickening of the buttocks and thighs and a subcutaneous deposit in the breasts. With this increase of fat there is a low blood pressure and a good or increased tolerance to carbohydrates. Sometimes there are other changes, which are possibly due to an associated diminution of the anterior lobe secretion, so that they may be small in size with late union of the epiphyses, softness of the skin, and no growth of hair. There is always a diminution in the sexual development. The genitalia remain small and the voice is high-pitched and squeaky and the thyroid small. It is probable that what Pearnsides has described as the "pudding-face type" is a mild degree of the same disease. There may be a slight general increase in the subcutaneous fat—the face is fat and rounded with red prominent cheeks, and the voice is high and piping. The thyroid is small and amenorrhoea is generally present. As in the Fröhlich's type there are frequently alterations in the visual fields which may, if left, progress to complete blindness.

Adiposis Dolorosa.

There is an increasing amount of evidence that a large number of the cases which have been described as adiposis dolorosa are in reality examples of hypopituitarism which have developed after adult life; they therefore bear the same relationship to Fröhlich's disease as acromegaly does to gigantism. Cushing quotes several cases in which lesions of the pituitary have been found under such circumstances, and Dercum himself has included certain mental changes as one of his four cardinal symptoms of the disease.

The disease is generally seen after middle age, and is more common in women. It is characterized by a rapid increase in weight, which is due to large irregular and frequently painful deposits of fat. The deposits may be diffuse in outline or may be more or less localized, so that they form large irregular lipomata. The deposition of the fat is very characteristic. It is almost wholly localized to the trunk and pelvis, while the face, neck, and extremities are as a rule free. The hands are not enlarged and the fingers are usually tapering. Sometimes the portions of the body above the waist will remain entirely free while the buttocks and thighs are enormously enlarged. In other cases there is also a big deposit in the back and shoulders, and sometimes even in the posterior aspects of the arms. There is frequently with this an increase in the sugar tolerance, and not uncommonly some local evidence of pressure, as shown by changes in vision. Occasionally there are well-marked evidences of general pressure, as shown by headache and drowsiness, and very frequently there is amenorrhoea.

Local Pressure Symptoms.

The most frequent change which occurs with the local pressure of the growth is an affection of vision. The pituitary gland, with so close a relationship to the optic tracts, chiasma, and nerves, is liable as it enlarges to press upon these

structures and give rise to changes in vision. Little will be said about these changes, as they will be described in detail by other contributors. It is sufficient to say that the most characteristic change is due to pressure upon the inner part of the optic tracts and the inner part of the chiasma, so that the fibres passing in the two nasal fields of the retina are those which are chiefly affected. In these circumstances patients will develop a bitemporal hemianopsia, and it will often be noted that they complain that they are unable to see objects on one side of them, and that they appear to be looking through opera glasses or through tubes. It must be remembered, however, that with some of the larger tumours of the gland the whole chiasma is pushed upwards and backwards. In these circumstances the pressure is more even, and the fibres running to the nasal fields will not be so much affected. As, however, the chiasma is drawn upwards the tumour will compress the two optic nerves in that portion of the circle of Willis which is formed by the two anterior cerebral and the anterior communicating arteries. There will thus be a constriction of both optic nerves, which explains why in some cases the patient will develop a complete optic neuritis or atrophy giving a general impairment or even complete loss of vision.

Much less frequently there is evidence of interference with the changes of the fifth nerve; the patient may then suffer from severe attacks of neuralgic pain on one or other side of the face, and there may be an area of hyperaesthesia limited to one or all of the divisions of the fifth nerve. In my own experience there has only been one case of diplopia and no example of any interference with the first, fourth, or sixth nerve. Cushing, however, states that in several of his cases there have been periods of double vision suggesting oculomotor implication, and in advanced cases an anesmia may be complete. These local pressure symptoms may or may not be associated with changes in the general metabolism.

General Pressure Symptoms.

The pituitary tumour, like all other intracranial tumours, will sooner or later give rise to evidences of a generally increased pressure, but it must be remembered that headache alone is not of necessity such an evidence. Severe local headache may be found quite apart from other signs of pressure, and may be due to pressure upon or erosion of the basisphenoid. On the other hand, tumours which are not entirely pituitary in origin may arise in the base of the brain and by pressure upon the pituitary may interfere with the functions of this gland and so give rise to changes in the metabolism. If the case be left for any length of time, evidences of general pressure, such as increased headache, mental dullness passing on to drowsiness, optic neuritis, and perhaps even slowing of the pulse, will be certain to appear. It must be remembered here also that although one of the strongest cases of evidence of a pituitary lesion is that presented by the x -ray appearances, a general intracranial pressure from some remote cause, or even a hydrocephalus, may give rise to a considerable enlargement of the pituitary fossa, and hence the condition may be mistaken for a primary tumour of the gland.

INDICATIONS FOR OPERATIVE TREATMENT.

It has been pointed out that cases both of hypersecretion and hyposecretion are generally due to a tumour or cyst, and thus both would seem amenable to surgical treatment. The first essential is therefore to exclude the possibility of a case of hypopituitarism being due to a primary atrophy of the gland. In such a case there would, of course, be no evidence of local pressure and an x -ray photograph would show a small fossa. These cases are not operated upon, for in the light of our present knowledge it would seem that removal of the gland would only increase the hypopituitarism. This opinion may later have to be altered, for it is interesting to note that two of my cases, one of which was an acromegaly, had the gland completely removed, and have not developed hypopituitarism; whereas another, who had Lorain's disease and also had the tumour and pituitary gland completely removed, has lost his symptoms of hypopituitarism although no gland extract has been administered. There is, however, another question which has to be considered, and that is a comparison of the dangers of operative treatment as compared with the danger of the disease. Some forms of acromegaly are very slowly progressive and may, in fact, after a certain period of time become stationary, so that the patient may live in comfort for many years. On the other hand, the operation must always be considered as a

serious one and at present has a relatively high mortality. For this reason the majority of physicians and surgeons would not advocate operative interference for simple hypo- or hyper-pituitarism. When future experience has reduced the mortality of surgical treatment it will probably be applied more frequently in this type of case. At present the indications for operation are:

1. The presence of some enlargement of the gland either from a tumour or cyst.
2. A rapid increase in the symptoms.
3. The presence of local pressure symptoms, especially diminution in the field of vision.
4. The presence of general pressure symptoms, such as headache, vomiting, or early optic neuritis.
5. The presence of glycosuria.

In regard to the presence of glycosuria it must be remembered that this is directly due to the lesion of the pituitary, and that very frequently by careful medical treatment and diet it may be eliminated, and if the operation be then performed it will not return, although medical treatment is not continued.

CHOICE OF OPERATION.

I do not propose to consider in detail the different methods of operative technique, for in my own experience one path of approach is so greatly superior to all others that it alone need be considered. At the present time the operation which is most frequently performed is the intranasal method of transphenoidal approach, but to my mind any form of approach through the sphenoid bone is incomplete and unsatisfactory. The opening is bound to be small and may give no idea of the size or position of the tumour. If there be a cyst it may be drained, but there is no evidence that it will not refill. A solid tumour can at best be scraped out piecemeal and therefore may recur. This method of approach must also, even if carefully performed by the subnasal route, be associated with a certain danger of sepsis. All these objections are absent when performing the operation by the transfrontal route. A perfect view may be obtained of the pituitary gland and its surrounding structures, the whole tumour can be carefully dissected free under direct vision, and a mass as large as or larger than a walnut can be taken away as a whole. Two objections are made to this route. The first is that it carries with it too high a primary mortality. In the past this has been so, but it is very largely due to the fact that operation has been delayed until the patient has developed increased intracranial pressure. In such circumstances any cranial operation is bound to carry with it a high mortality. If the operation is carried out before the onset of this complication there is no reason why there should be any mortality at all. Of my six cases where this operation has been performed two died as an immediate result, and both of those at the time had an increased intracranial pressure. Even with this intracranial pressure the transfrontal route shows a mortality no greater than that by the extracranial route, for Frazier has collected sixty-four tumours operated upon by the extracranial method with twenty-four deaths.

The other objection which has been raised to this method is that good access cannot be obtained to the floor of the pituitary fossa, and it is therefore usually stated that if the x rays reveal a deep erosion of the fossa the transphenoidal route should be applied; whereas, if the x rays indicate an upward growth, the intracranial route is the one of choice. I believe that this suggestion is quite erroneous. In every case where I have operated by the transfrontal route I have been able to obtain access to the floor of the fossa, and by elevating the brain a good view of the dural floor has been obtained. The method which I advocate is a modification of the operation published by Frazier, which itself was a modification of the technique of the methods used by Krause and McArthur. The actual steps are as follows:

The approach is always carried out on the side of which the vision is most affected, for it may happen that the operative steps may cause a certain amount of trauma of the optic nerve, and if the eye is already blind on this side no harm will be caused.

A rectangular incision is made. It commences in the temporal region just above the zygoma and passes along the line of the eyebrow to the middle of the forehead. From here a second limb passes vertically upwards for a distance of about four inches, and from this upper extremity a third incision is made parallel to and of the same length as the first. The soft tissues are then elevated from the four corners of the flap marked out, and openings are made with

will give rise to more marked mental changes; but any subacute and persistent alteration will be definitely reflected in the mental outlook of the individual. Every organ, and indeed every structure of the body, must be represented in the field of consciousness, but the stimuli arising from them only arouse consciousness of their existence when they are raised above a normal intensity. On the other hand, it is possible to obtain a relative hyperaesthesia by the lowering of sensitivity in the surrounding tissues. Pain—one of the most common changes in sensation—has been regarded from the philosophic standpoint as something of value to the organism and as tending to favour its survival. But pain is not always related, either by its cause or by its persistency, with some definite abnormality of which it is a more or less precise indication of constant value. Pain tends to persist long after the original cause has ceased to operate, and the longer it exists the more difficult it is to relieve. Pain evokes the same physical changes that are aroused by emotion, and the energy that must be dissipated by the mobilizing of these forces must sooner or later lead to exhaustion, which in some persons is more noticeable on the physical side, and in others in changes in the mental attitude.

Apart from severe pain there is no symptom so capable of initiating bad mental habits as discomfort. There are all good examples of this, but some of them lead to permanent ill health unless understood and suitably relieved; acrophagy is an instance. During the last decade, and more especially owing to the work of Dejerine, emotion has come to be regarded as one of the most important factors in the mental and physical health of an individual. It may arise from an external or an internal cause. By its suddenness or by its intensity emotion may completely overthrow the equilibrium of the subject who experiences it. This condition may on rare occasions be lasting, though it is more common to have a gradual return to normal self, but this regaining of conscious judgement is by no means even, and is often interrupted by a series of relapses. Even a lesser emotion if it lasts may set up a very definite "preoccupation" which in turn may lead to some mental change.

Every person has his own way of reacting to emotional excitement, and in some instances an external emotional stimulus, such as the shock of hearing bad news, only develops its full potency after being reinforced by internal emotion. A common form in which this type is to be observed in relation to physical disease is when a patient has been told some disquieting news regarding his health or when he may have inferred from some gesture or expression of his medical adviser that his condition is serious. Whether the emotion is severe or slight, if it occasions loss of intellectual control it tends to the establishing of a neurasthenic state, which in turn leads to a lessening of the power of adaptation in the person so affected. In some cases the neurasthenic condition may be complex, but in others it may be limited to the disorder of function of some organ of the body. To this type belong those individuals who develop fears regarding their heart, their lungs, or indeed any organ of the body, and this condition may persist long after the original emotional cause has disappeared and the patient has regained full intellectual control. The ill person is very suggestible, especially towards a morbid outlook, and any remark made by a physician may be so exaggerated and distorted as to lead to a preoccupation of an important kind.

Again, the number of persons who break down either immediately after an operation or some weeks later is larger than some may suppose, and many of these can be traced back to the emotional shock that the individual received when he was told that an operation was necessary. Emotional shock leads to preoccupation, and preoccupation leads to sleeplessness with its resultant nervous and mental fatigue. Highly hypersensitive persons should not be told of the need of an operation long before this is to be performed, and after any discussion of this nature has taken place the sleep of the patient should be carefully watched and sedatives administered if necessary. Also with this class of case violent purging a few hours before the operation should be avoided if possible, as this increases the danger of a nervous collapse with mental confusion after the operation. Crile and Lower conclude that surgical shock is a state of exhaustion which leads to changes in the brain cells, the liver, and the adrenals. They recognize that there is no distinction between emotional shock and shock produced by other means; the clinical phenomena are practically the same; they state that the cellular changes are apparently identical, and that the condition is brought about by an intracellular acidosis.

Many women, especially those in ill health or from some cause in a fatigued state—whether this is from the disturbed sleep so common in the later months of pregnancy or from some stress—are in a highly unstable state by the time that labour begins. The emotion which is always more or less present at this stage may pass the normal limits either from dread of the ordeal which confronts the patient or from the actual suffering at the time the baby is born. Such women should be protected by taking care that the hours of suffering and the intensity of it are limited, and yet too often these precautions are ignored, largely on the false argument that the process is a purely physiological one. An emotional disturbance of this kind may lead to years of ill health even if the patient escapes a severe mental breakdown. Emotion that has once been aroused may not settle down, and it nearly always leaves the person more susceptible to other emotional shocks.

Both physicians and surgeons know how devastating is fear, and how some patients who face an operation or an illness under this influence die without any apparent reason. To remove such fear, if it is possible—and it often is possible—is as urgent as it would be to control persistent vomiting, and yet in practice it is common to see the panic being accepted by the medical attendant in a fatalistic way and evoking nothing more than a regret that his patient is so foolishly nervous. The fearful person can usually be reassured, but he who would undertake to do this will best succeed if he has some knowledge of mind and its working. Some medical men, under the idea that they are bracing up their patient, do infinite harm by their remarks, especially if these include words of reproach. It is true that one fear may for the moment replace another fear, but I need hardly say that this is highly unscientific and is no more a remedy than is a lavish expenditure of sympathy. Fear and anxiety bring about a condition of mono-ideaism in which the patient is unable to turn his attention away from the morbid thought which seems to fill his whole mind. If the preoccupation continues, it will begin to interfere with sleep, and Crile found that sleep was the only certain means of restoring the exhausted cells in the brain or liver and adrenals.

As a profession we have become unduly apprehensive of giving hypnotics. Experience has taught me how dangerous is this outlook, for insufficient sleep, especially under certain conditions, is infinitely more damaging than any drug; and as for the danger of inducing a habit by giving a hypnotic, if we omit the morphine and opium group, which should not be given, the risk is infinitesimally small. The physician who puts off prescribing a hypnotic as long as possible is the man who may bring about the habit he so much dreads, for he has by his methods permitted the patient to become obsessed by fear that he will not sleep, and when at last a drug is given and sleep is obtained the patient is terrified by the experience he has passed through of ever again having a sleepless night. Insomnia that is quickly relieved leaves no such memories, neither does it make the patient rely upon any artificial aid.

My experience strongly favours the view that a psychoneurosis may develop into a psychosis; but for the moment the point is that any mental symptoms arising in association with physical disease should receive the consideration that their presence merits. As in other matters of life the proportion is divided into two portions: the facts, or, as it is in medicine, the definite symptoms, and the inference or deduction that we make regarding those facts or symptoms. Now the body in health occasions few if any conscious sensations, and in consequence when they do arise the patient is apt to place his own interpretation upon them, and unfortunately the explanation is too often wrong. Altered sensation may be so severe as to occasion a patient to construct a definite delusion regarding it, but it is more common for him to have some fear as a result. This in turn may set up an emotive state, and this psychic reinforcement, when it occurs, greatly enhances the importance and the severity of the condition. Head has pointed out the varied moods that may arise in conjunction with pain of the reflected visceral type and the superficial tenderness which accompanies it. He states that "although reflected visceral pain seems to be the one universal concomitant of those mental changes in cases of visceral disease amongst sane persons, other factors predispose to their appearance"; but in the cases upon which he based his investigations he rigidly excluded all those in which there was an heredity of insanity or epilepsy. In addition to altered moods Head found that under certain conditions some persons suffering from visceral disease

are liable to develop hallucinations of sight, of hearing, and of smell. He further found in those persons who had visual hallucinations that superficial tenderness of the visceral reflected type was present over the forehead in every one of the cases, whereas in those who exhibited auditory hallucinations the tenderness was present in the vertex and parietal regions. The importance of the condition is not so much the sensory disturbance as the emotion that such a phenomenon may set up in the patient. It does not require a great imagination to appreciate what a disturbing effect these sudden hallucinations may have upon a highly sensitive person, and it is no cause for surprise that the inference that many of them draw is that their mind may be going. As they are sane persons their fear may be quickly allayed when the true nature of the disturbance is explained to them; but the tragedy of the situation is that, owing to the neglect of a systematic investigation of the mental aspect of a case by the general physician, the latter is often not conversant with the phenomena we are describing, and either he is unable to reassure his patient or, what is worse, he conveys to him the doubts that he has in his own mind. Many of these hallucinations are hypnagogic and occur when the patient is in a half-asleep and half-awake state. On the auditory side the sensory disturbances may take the form of tapping, knocking, bells, musical notes, name called, and even at times a few words. It is advisable in these cases to give one small dose of bromide daily to lessen the nervous reflex irritability, and if there is any tendency to sleeplessness this should be promptly relieved by sedatives.

Head states that when visual hallucinations arise in visceral disease the object appears white, black, or grey, never coloured or even tinted. He found that almost every patient felt frightened with the first hallucination of vision, as is usual with the auditory, but that if they were frequently repeated self-control returned. This again must largely depend upon the reassurance that should be given by the medical attendant.

Visual hallucinations may be and are a prominent symptom often of diagnostic value in states of toxæmia; the hallucinations may be only a part of a general altered mental state, for, if the poison is active, the patient usually soon becomes very confused, and may even be delirious. Nevertheless it is important to differentiate these cases from other types of mental disorder, as the mental changes may be very evanescent and pass away quickly when the intoxication is relieved. In such cases the natural resistance may be lowered and the tendency of the patient may be to react by mental changes. It is very necessary to recognize the syndrome of symptoms which arise in these toxæmic conditions—as, for example, their presence may be the first indication of pus.

Mental disorder is not haphazard in character, and the better we understand the grouping of its symptoms the more accurate we shall become in the diagnosis and prognosis of any given case. We are only upon the threshold of understanding the effect of any foreign protein taken into the body, but both clinically and experimentally it is recognized that striking effects may follow quite insignificant doses. It must be borne in mind that the effect may be more physical than mental, or vice versa, and consequently there must be every gradation between the two, and though the bodily symptoms may be the more common it is none the less important to seek for and to note any functional nervous change. Any poison is capable of producing mental disorder provided the person who takes it, by his special idiosyncrasy, reacts to it. The danger of regarding physical and mental disease in separate categories according to which group of symptoms is the more in evidence must be avoided.

Too little heed is given to gesture, expression, and posture. There are well-recognized diseases in which characteristic changes in any one or more of these are noted, and they may constitute important links in the syndrome of symptoms which go to establish the diagnosis of such diseases, but, generally speaking, little or no remark is made about them. Yet gesture language will convey as much as, if not more than, words, for these may be misleading, while gesture seldom is, for the latter is complex and it is the outward and visible sign of inward sensation and emotion. Maudsley, in his book on *Pathology of Mind*, says: "What is mind-reading but muscle-reading through movements so fine as to be discernible only to a practised sensibility?" Physicians of long experience acquire it, but it is a matter of too much importance to be left for time to teach and the observation of the student should be trained to appreciate it. He learns

that physical pain, especially of the visceral type, is shown by the lower part of the face, but the tremor set up by strong and intermittent nerve currents transmitted to the various muscles may be of almost equal importance. The man who can observe can inquire, but he who sees but does not perceive is left in ignorance unless the information is disclosed to him by the patient. Further, even if noted, evidence of emotion, such as tremor and the like, is commonly explained away without any real investigation being made as to whether it should be regarded as a matter of consequence. Persistent disorder of conduct usually leads to further inquiry unless it is decided that it is purely hysterical, but owing to the loose way in which this term is frequently used abnormal behaviour may be wrongly regarded. The conduct may become undisciplined, and with this there may be a general restlessness; this is common in some forms of heart disease, and even more so in exophthalmic goitre. These may be the first symptoms to attract attention, and in any case they should never be looked upon as unimportant. Conduct may be disordered either by overactivity or by underactivity. The muscular response may take place with the inertness of the response may be such that even with the response is small, while between these two extremes stand infinite variations. A change of conduct which originates in the course of some disease may persist after the latter has passed away unless steps are taken to remedy it, for such a change may become a pure habit. If, on the other hand, the attention of the patient is drawn to the symptom and it is treated as part of the illness, it not uncommonly disappears as recovery takes place.

Disorders of the endocrine system are examples of the close relationship of mind and body. The disturbance may begin either from the psychological or from the physical side. The stimulation of the sympathetic nervous system and of its adjuncts, the adrenals and the thyroid, results in a mobilizing and rapid expenditure of reserves, and for the time a heightening of all the vital processes. It is a katabolic action, and yet, owing to the quickening of metabolism, it is at first associated with a feeling of well-being which may be so strong as to produce a mildly exalted state. But, should this continue, exhaustion, with all its usual mental and physical concomitants, must sooner or later result. Apart from emotion the feeling tones associated with disease are important to note and understand, otherwise the effective changes in the patient may be seriously misleading. One of the most remarkable and yet most common instances is the buoyancy of spirits to be observed in certain patients on the days immediately following an operation. Although this brightness may to a small extent be due to the relief of mind that the ordeal which has been weighing heavily on the patient is now successfully past, another cause, if certain authorities are correct, would seem to lie in the stimulation of the sympathetic nervous system and the endocrine glands, one of whose functions, it is said, is to protect the organism in time of stress. Too often one sees this cheerfulness misinterpreted, and the physician or surgeon who looks for a rapid result welcomes this attitude as an indication of returning health, and all too frequently it encourages him to abandon the rules of carefulness and to permit his patient to do things which hasten the onset and increase the severity of the exhaustion which must follow. If a patient is depressed or rudely elated, an endeavour should be made to discover the cause; I do not refer to states of melancholia and mania, which are usually spoken of as insane conditions. There are many variations in affective tone; some may be temperamental and some rhythmic, but others may be due to metabolism changes. I have long remarked upon the sense of well-being which is so commonly associated with a fall in the body weight; it is probably one of the most deceptive mental attitudes in life. During the war many of the civilian population who lost considerable body weight owing to the restriction of food commented on how much better they were for it; some, no doubt, were better because their reserves were abundant, but others learnt to their sorrow that this betterness was ephemeral and that a period of ill health awaited them.

The mental reaction of every person to disease is individual; it is always the same for that person, and is not haphazard, but follows rules and progresses in an orderly way. The more elemental the mind the easier the problem becomes, and for this reason to study the mental reactions of children to disease is the most helpful method of approach, for in later life the experiences that an adult has passed through add their colouring to the fundamentals. The tendency, or indeed

I might say the universal custom, has been to regard man as he appears; we have a face-value standard of mental and physical health, but we never rely upon the latter in the same way as we are prepared to accept the former. If the bodily health together with the functions of such organs as we consider to be important are satisfactory, the patient is regarded as an A man, notwithstanding that the mental outlook may be scarred with former illness. There is no better example of the danger of specializing than the study of mental and physical medicine. Theories become practice, and man has been viewed from these two standpoints, which at some periods have been so divorced as to have little or nothing to do with each other. The *have been slowly linking these* it is the duty now of all clinicians to widen their vision and not only to make use of the beginnings that have already been made, but to add to their knowledge by a systematic investigation of mind states in all physical disease. We shall find that mental symptoms have their value, and that, whilst some are primarily harmful, others may be largely, if not entirely, protective to the organism, and may form part of its armament in its struggle to survive. But, as with all functional disturbance, they may remain long after their purpose has ceased to exist. Habit is the state towards which everything is working, and it is one of the duties of the physician to see that baneful influences do not persist if it is possible to correct them. The physical hygiene of the future must include a knowledge of mental hygiene, just as mental hygiene must take note of the welfare of the body. From this several advantages will accrue: mental processes will be better understood and mental changes will become matter of commonplace; fears of insanity will be replaced by an enlightened understanding, and the incidence of the graver forms of mental disorder will be lessened.

THE TREATMENT OF RODENT ULCER BY CHROMIC ACID SOLUTION.

BY

A. DINGWALL KENNEDY, M.D.,
WICK, CAITHNESS.

THE medical man who practises in a district remote from large hospital centres is often faced with difficulties in the way of treatment not experienced by his more favourably placed colleagues. When, for example, the case is one requiring special treatment, as with x rays or radium, and the nearest hospital equipped with the necessary outfit is several hundred miles away, the problem becomes very real. To the working man the expense of the journey and the time lost from work mean a great deal, and, unless his life is at stake, he must simply do without the treatment and go on using such palliative measures as can be obtained locally.

Rodent ulcer is a disease of local malignancy which can be successfully treated by excision, by escharotics, or by radium. The two former involve the destruction of the healthy along with the diseased tissues, while the latter is not always available. Many patients object to operation, and in some cases the site of the ulcer renders operation difficult, if not impossible, without leaving a disfiguring scar. Excision of a rodent ulcer from the lower eyelid, for instance, may be followed by an ectropion more unsightly if less serious than the original ulcer.

The treatment of rodent ulcer by the application of chromic acid solution, 10 per cent. in distilled water, was suggested to me in 1910 by Sir George T. Beatson, senior consulting surgeon to the Royal Cancer Hospital, Glasgow. I began practice in Wick a few months later, and during the following four years treated 19 cases successfully. I intended publishing my results then, but five years of war intervened. Since 1919 I have treated 6 other cases, and am satisfied that the results justify this article. In only one case was the diagnosis confirmed histologically, but the history and appearance of the others made the diagnosis clinically certain. With two exceptions, all the cases were comparatively early—that is to say, ulceration had taken place, but the soft tissues only were invaded. In one the glabella and part of the septum were destroyed and the nasal bones exposed; after four months' treatment the raw surfaces were covered by healthy granulating tissue, except a small portion of the floor of the nose. Unfortunately this patient died of pneumonia before treatment could be completed. In the other case the ulcer was small and situated on the right ala

nasi, penetrating to the cartilage, which formed its base. This case proved most intractable, and eleven months' treatment was required to effect a cure, but during that time the patient did not lose a single day off work, and now, twelve months later, a slightly dimpled scar is all that remains.

As all the cases were treated in the same manner I will describe one more before proceeding to the details of the treatment.

The patient, a man aged 70, consulted me in November, 1919, about an ulcer of six years' duration affecting the lower eyelid towards the inner canthus. In shape it was roughly elliptical and its upper border within a quarter of an inch of the margin of the lid. Removal of the crust which covered the floor of the ulcer was followed by purulent discharge. He had no pain, but a hanting fear that sooner or later his eye would become affected. After four and a half months' treatment the ulcer was healed. It had filled up and there was only a slight depression to indicate where it had been. The scar was supple, and hardly distinguishable from the surrounding skin. There was no contraction, and consequently no ectropion.

Treatment is carried out as follows: When the crust, if any, has been removed and the floor of the ulcer cleansed with plain sterile water, chromic acid solution is applied to it and to the surrounding skin by means of a fine camel-hair brush. This is repeated daily until the patient complains of pain coming on about an hour after treatment and usually lasting an hour. Each succeeding day the pain is of longer duration and signs of irritation appear. The surrounding skin becomes red and oedematous, and at this stage, varying from the fifth to the tenth day, the treatment should be discontinued and a bland ointment substituted till the pain and inflammation subside. Plain vaseline or equal parts of boric and zinc ointments may be used. It is immaterial what emollient is chosen so long as the active treatment is interrupted at intervals regulated by the degree of pain and irritation present. During the first few weeks the ulcer may actually increase in size and depth, and it is well to warn the patient of this before beginning treatment; otherwise he is apt to conclude that he is getting worse instead of better. In my earlier cases I found that repeated application of the chromic acid solution was not infrequently followed by the formation of a dense firmly adherent crust exceedingly painful to remove. To obviate this I now apply to the floor of the ulcer a pledget of cotton-wool which absorbs the exudate and is easily changed next day. When the extreme limit of malignant invasion of the surrounding skin has been reached further changes in the appearance of the ulcer take place. Its raised border becomes flattened and covered with healthy-looking epithelium which gradually advances along the floor of the ulcer towards the centre. The chromic acid applications are now attended by less pain, and eventually the ulcer appears to be completely healed. Should this occur during the use of the ointment chromic acid should again be applied for a few days, and if the disease has been eradicated no effect whatever will be produced. Should, however, the apparently healthy epithelium thinly cover tissue in which malignant elements are still present it will break down, and a continuation of the treatment will be necessary. Chromic acid diluted to 10 per cent. strength, while inimical to rodent ulcer cells, does not affect those of healthy tissue however tender.

On two occasions I have tried its effect on epithelioma of the lip. In one case the patient refused operation, and within a fortnight of the commencement of treatment the ulcer had doubled in size and, at the urgent request of the patient, was dealt with surgically. The other case was one of incipient epithelioma at the junction of the upper and lower lips with extensive leucoplakia of both lips. The chromic acid solution was employed with a view to getting rid of this before operation. It was eminently successful so far as the leucoplakia was concerned, but here again the epitheliomatous ulcer was stimulated to rapid growth and was shortly afterwards effectively removed by Mr. Henry Wade of Edinburgh.

I would like at this point to mention an instance not of rodent ulcer, but with the same tendency to local malignancy, successfully treated on similar lines.

The patient, a woman over 70 years of age, suffered from a papillomatous growth of the left cheek of several years' duration. She had been operated on six times, with a recurrence on each occasion at the end of three to seven months. On her refusal to submit to further surgical treatment she was sent in 1909 for radium treatment under the care of Dr. Dawson Turner of Edinburgh. She was treated for 43.3 milligram hours, and left hospital apparently cured, but five months later there was a recurrence at three separate parts of the scar. I saw her a year later and after

three months' treatment with chromic acid the growth again disappeared. Nine years later she died, but there had been no recurrence.

This case illustrates the importance of a form of treatment easily accessible. Had the patient resided near the centre where radium treatment was carried out, instead of three hundred miles away, the recurrence could have been dealt with at once. As it was, she could not afford a second journey. It may be argued that in widely scattered districts, where the patient lives ten or twenty miles from his doctor, this treatment is almost as inaccessible as radium. I had one such case.

A man, aged 60, came to me complaining of an ulcer which he had noticed three years previously and which he had endeavoured to cure by many and varied ointments of the proprietary type—and his ulcer slowly increased in size. It was situated at the angle formed by the lobe of the right ear with the skin extending from it towards the angle of the jaw and measured about three-quarters of an inch in diameter. As he informed me that it was quite impossible for him to attend daily for treatment I gave him a prescription and wrote down in detail the procedure to be followed, asking him to report weekly for observation and further guidance. I did not see him again for two months, and by that time the ulcer had almost healed. Eighteen months later he dropped in casually to tell me that his ulcer had completely healed a month after I had last seen him and had not again broken down.

The duration of the treatment where the soft tissues only are affected averages three and a half months. Where bone and cartilage are invaded the patients should be strongly urged to go where more effective treatment can be obtained. At the present day no patient suffering from rodent ulcer should be allowed to reach that stage.

Of the various local remedies that have been used successfully in the treatment of rodent ulcer, and whose action, like that of 10 per cent. chromic acid solution, is selective, salicylic acid, pyrogallol, and arsenious acid may be mentioned. Of these, arsenious acid, according to Dr. Norman Walker² of Edinburgh, has given most satisfactory results. In his *Introduction to Dermatology* he discusses very fully the treatment of rodent ulcer, and, in describing the use of drugs whose action is caustic and selective, he rightly emphasizes the necessity for care in the choice of the drug as well as in its application. Of the effect of the arsenious acid preparation favoured by him he says: "In twenty-four hours the part has swollen up and the pain experienced is very severe, so severe that it is often necessary to give the patient morphine." Farther on he says, "In many cases one course of this treatment is successful." I admit that, in comparison, the course of treatment by 10 per cent. chromic acid solution is long and even tedious, but it is less drastic in its action, the onset of pain is more gradual and need never be permitted to become unbearable. Its advantages discount both the length of time taken to effect a cure and the slight pain and discomfort experienced during its exhibition. The remedy is cheap, and it is easy to use. The destruction of tissue following its use is limited to diseased elements. The patient is spared the expense of a long railway journey and is able to continue at work throughout the treatment. The resulting scar, wherever situated, is soft and pliable, and there is no contraction with consequent disfigurement. And finally, should recurrence take place, the patient has the satisfaction of knowing that a simple and effective remedy is immediately available.

PROPHYLACTIC RECTIFICATION AND VERSION AT THE ANTE-NATAL CLINIC.

BY

J. W. BALLANTYNE, M.D., F.R.C.P.E.,

PHYSICIAN IN CHARGE OF THE ANTE-NATAL AND VENEREAL DISEASE DEPARTMENTS IN THE EDINBURGH ROYAL MATERNITY HOSPITAL.

Down to the close of 1921 the correction of malpositions (right occipito-posterior) and malpresentations (pelvic and transverse presentations) in the ante-natal department of the Edinburgh Royal Maternity Hospital had attained only a partial success. There were numerous cases, especially of malpositions (chiefly right occipito-posterior) in which neither one-handed nor two-handed palpation applied by the abdomen or the vagina or by both routes sufficed to bring the back of

the foetus round to the anterior aspect of the mother. Postural plans were also experimented with—for instance, a modified Trondelenburg position was used in some cases in the hope that the presenting part would slip out of the pelvic brim and become movable above it; but success was only occasional. Dr. F. J. Browne and I often talked over the subject, but without devising anything which was wholly satisfactory.

On November 12th, 1921, Dr. R. C. Buist of Dundee published in the *BRITISH MEDICAL JOURNAL* (p. 782) "A note on the early recognition and corrective treatment of occipito-posterior positions," in which he described the method of rectification by means of towel pads. There were some details in the procedure which were not clear to me; so I got into communication with Dr. Buist, who was kind enough to explain and illustrate the method by diagrams. From the beginning of the present year (1922) the method by pads has been employed in the ante-natal department for the correction of occipito-posterior positions of the head. The results for the six months from April 1st to September 30th, 1922, have been most satisfactory. During this period 509 expectant mothers attended the ante-natal clinic as new cases. Amongst these there were 26 instances of right occipito-posterior position of the foetal head, and of these 24 were rectified by pads into anterior positions, whilst 2 remained posterior, notwithstanding the treatment. In most of the cases the rectification was into the right occipito-anterior position, but in some the rotation was continued until the head was found to lie in the left occipito-anterior position. In one case which has occurred since the end of September the original position was diagnosed as left occipito-posterior and pads were applied, the rolled one on the left side and the flat one on the right; on the following day it was found that the presentation was a breech, and external version was then performed, producing a right occipito-anterior position. This was the only occasion on which the application of the pads in posterior vertex positions was followed by the production of a pelvic presentation.

The method adopted was that recommended and described by Dr. Buist as follows:

"A binder is laid under the patient and two towel pads are prepared. The first is rolled to about the thickness of a forearm, the second is folded to a flat pad 6 or 7 inches square. The rolled pad is pinned to the binder in such a position that when the binder is firmly secured the pad will lie close in front of the anterior superior iliac spine behind and parallel to the trunk. The flat pad is pinned so as to lie on the limbs, pressing them backwards. It is sometimes useful to roll the patient to the side opposite the trunk and by hand bring the trunk as far as may be over to that side. The binder is then pulled firmly home."

In the Edinburgh clinic it has rarely been found necessary to take the patient into hospital for the rectification. The malposition is detected at the clinic; the patient is asked to return the next morning and to bring with her a binder, two towels, and safety pins; the pad and binder are then applied and the patient is allowed, after a short rest, to go to her home; she returns the next morning, when it is usually found that the position is anterior. Occasionally the pads have to be reapplied, rectification not having occurred at once. As has been said, the procedure only failed twice. Such failures are to be ascribed to the late date in pregnancy which has been reached, and the low level of the foetal head in the mother's pelvis. Very rarely was the posterior position reassumed after rectification.

It is difficult to find a completely satisfactory explanation for the corrective effect of the pads. Probably the rolled pad simply makes the existing position an uncomfortable one for the foetus; he will be mobilized, and, using the flat square pad to press his limbs against, will move into the position in which he is able to lie at rest, the right or the left anterior. I hardly believe it can be claimed that the rolled pad gets in behind the foetal back in the right occipito-posterior position and pushes it forward. The cases in which the position is found to be the left anterior are probably those in which the pads have produced a marked reaction by the foetus, and the back has thus been carried right across the abdomen. It is unnecessary to emphasize the great advantage this method of dealing with occipito-posterior positions possesses over the difficult and often uncertain plans of rectification applicable in labour; personal experience enables me to say with assurance that it is also much better than any method of manual replacement in pregnancy.

In the series of 509 pregnancy cases in the six months referred to 56 pelvic presentations were detected. In

11 of these cases no attempt at version was made as the pregnancy had only attained the sixth or seventh month, and it was thought that they might safely be left for a little longer. In 14 cephalic version was performed by external manipulation, sometimes by one and on other occasions by two operators. There were 7 cases in which version was found to be so difficult that chloroform had to be administered, with the result that success was obtained in 6. In 3 other cases attempts were abandoned owing to small amount of liquor amnii and close apposition of the uterus to the foetus. In 19 cases spontaneous version occurred. In 2 the patient did not return to the clinic. In this way the 56 cases were accounted for. There were 3 cases of transverso presentation in the 509 patients. Cephalic version was carried out in them all by external manipulation. Towel pads may be used in difficult breech and transverso presentations.

A CASE OF CONVERSION NEUROSIS.

BY

PHILIP C. LIVINGSTON, M.R.C.S., D.P.H.,

MEDICAL OFFICER IN CHARGE OF MEDICAL RESEARCH, R.A.F., INDIA.

WHILE doing the duties of staff surgeon in Ambala, India, I was called out early one morning to see a lady, aged 34, said to be acutely ill. On arrival I gathered that she had been having a series of fits which appeared superficially to resemble epileptic seizures.

When first I saw her she was just coming round from a second fit, and had gained a drowsy consciousness. She had incontinence of urine, rigid muscular contractions, and cyanosis. The temperature was 103° F., pulse full in volume. I learned that the day before, at about 11 a.m., she had gone into the bazaar wearing a very flimsy hat, and had come back with a severe headache which persisted throughout the day and night. A "touch of the sun" naturally suggested itself, particularly as that summer was an exceptionally hot one (about 108° F. early April, shade temperature at noon). I had the room darkened and cooled and a cold pack put to her head. The temperature and her general state did not seem to call for any other treatment. I eliminated malaria by film examinations. She had no more fits, and passed out of my care on departing to a hill station for the rest of the summer.

I was called again to see her in the following September. During her stay at the hill station she had had three severe attacks of a similar nature to the first, each more alarming than the one before, with longer periods of unconsciousness. The present was the fourth in five months. I found her on this occasion practically unconscious, the eyes turned upwards, the lips blue, the teeth still set (tongue not bitten as means to stop this had been employed). She had had a succession of four fits during the night, and was clearly feeling the strain. I admitted her immediately into the family hospital of which I had charge and asked the sisters to watch her closely and to report to me any further fits regarding the attacks. She was kept in bed, and given a strong triple bromide mixture. The fits, each one less severe than its predecessor, and under the influence of the bromides quieted down by the following day. The fits certainly appeared practically identical with those seen during an epileptic seizure. There was no family history of epilepsy or fits of any kind. Another blood film examination proved negative to malaria, and showed nothing abnormal in the differential count. Specific disease was excluded. I examined the central nervous system with extreme care. Nothing could be found beyond a slight increase in the knee-jerks.

Closer examination into her domestic life brought out the fact that her fits always corresponded with periods of worry about her two children during the absence of her husband on tour. The fits came on when he came back or just prior to his return—that is, when the tension of solitude was relieved. My patient passed rather a secluded life and saw very few people, although she lived well inside the cantonment.

Treatment.

The case here assumed a new aspect. I talked with her for a long while in private and led her towards the solution of her problem, which she eventually solved to her own satisfaction. She would never live again without a companion while her husband was away. This was the first step. Next came the consideration of drugs. Bromides I put immediately out of court in view of the fact that the case did not call for depression but healthy stimulation. I therefore put her on a series of injections (twelve in all) of the glycerophosphate compound put up in ampoules by Parke, Davis, and Co. During the full course her husband remained at home. The result was excellent. She felt inwardly much fitter—"never better for years," as she described it—and ceased to worry over her domestic problem.

Her husband went on tour shortly afterwards and returned to find her quite well. A companion stayed with her during his absence. Only once while he was away (she had again elected to live alone on three successive occasions) did she have any signs of recurrence. I was called in and found that she had been alone for

nearly two weeks at a time when the political situation was causing us all some anxiety out here. She had three slight fits, not to be compared in severity with those seen previous to treatment. Again she settled down quickly and has not had any trouble since. I have now lost sight of her.

In a space of about nine months after the above treatment she had only one slight recurrence under great mental provocation.

This case I think is rather exceptional, (a) in virtue of the fact that the weakness caused through exposure to the sun should become by "conversion" the expression of a psychoneurosis and continue as such; (b) the vast improvement in the case after a strong tonic, backed up by the patient's own solution of her problem; (c) the complete lack of previous or family history pointing to any disorders of this nature.

NINETIETH ANNUAL MEETING

OF THE

British Medical Association.

Held at Glasgow, July, 1922.

PROCEEDINGS OF SECTIONS.

SECTION OF DISEASES OF CHILDREN.

Sir HERBERT F. WATERHOUSE, M.D., F.R.C.S., President.

DISCUSSION ON THE ETIOLOGY OF RICKETS.*

OPENING PAPERS.

I.—LEONARD FINDLAY, M.D., D.Sc.,

Visiting Physician, Royal Hospital for Sick Children, Glasgow.

It is an interesting coincidence that on the return of the British Medical Association to Glasgow after a lapse of thirty-four years rickets should again form the subject of discussion by the Section devoted to the study of diseases of children. One appreciates the appropriateness of the choice, since rickets is a disease specially prevalent under industrial conditions, and probably no city in the kingdom possesses these in a more marked degree than does Glasgow. For this very reason the disease has naturally always interested Glasgow's students of medicine. The name of our distinguished President, as you are all aware, is associated not only with one of the most characteristic manifestations of the disease (MacEwen's tibial spine) but also with an operation for the rectification of the rachitic deformities. Two important investigations into its presence or absence in India, and the reasons therefor, have been carried out by Glasgow graduates (Huntly¹ and Hutchison²), and it is needless to remind you that within recent years the Glasgow school has earned for itself a certain notoriety on account of the interest which it has evinced in the malady.

Though the two meetings are alike in the choice of subject, the present debate differs from the one of thirty-four years ago in that it is a conjoint one between the physiologists and the pediatricists. This is of course in consequence of the great amount of experimental work which, during the intervening years, has been done to elucidate the pathology of the disease, and the lion's share of this stands to the credit of the physiologist.

Although there is nothing farther from my intention than to belittle animal experimentation, as I appreciate only too well the great benefits which have accrued to medicine in consequence, and indeed much of my own humble energies have been expended in this direction, yet the final battle regarding the etiology of rickets, at least human rickets, must be fought out in the clinical field. It is the admission of this fact, I take it, which is responsible for the onerous and at the same time honourable duty of opening the discussion falling upon me, a clinician.

Clinical Generalizations.

In the life history of human rickets there are several broad facts with which any theory of its origin must be reconciled before it would be justifiable to adopt it as the correct

* Joint Discussion with the Section of Physiology.

explanation of its pathogenesis. In the first place, rickets has a special geographical distribution; this after all may mean nothing more than that it simply follows the distribution of industrialism. It is a disease, too, which is never found in races living under natural conditions, but which may become exceedingly rife among those same people when they adopt the habits of civilized man, as is evidenced in the case of the West African negro in New York and other American cities.

In the second place, the disease presents a marked seasonal incidence. This is a point of considerable importance in evaluating any clinical prophylactic or therapeutic test. This is apparent from Dr. Helen Mackay's study of the effect of cod-liver oil and other fats in the treatment of the disease, and is also well borne out in the clinical investigations which Dr. J. D. Galbraith is at present carrying out in my own department.

In the third place, there is the broad fact that rickets is a disease of the poor, at least so far as Europe and America are concerned. Dr. Hutchison² has recently shown that in India, contrary to what prevails here, rickets is a disease of the wealthy. I know, of course, that there are many clinicians who do not consider that even in this country the disease is limited to the poor, and who hold that the children of the well-to-do also frequently suffer. They usually admit, however, that the disease under these conditions is much less severe and more amenable to treatment. In fact, one often hears employed the expression "prurachitic stage," whatever that may be. The whole point of course turns on the matter of diagnosis. Personally I am unable to make a certain diagnosis of rickets in the absence of either definite naked-eye or x-ray changes of the bones, and I would only ask if those clinicians who believe that rickets occurs in the better classes frequently meet with the characteristic x-ray appearances in these supposed examples of the condition. For any discussion on the cause or cure of a disease to be fruitful it is essential that there be agreement on what constitutes that condition, and though in the present case there may be some difference of opinion regarding the question of absolute immunity of the better classes, there is, I suppose, general agreement regarding the relative immunity enjoyed by that class—a fact which, for the purposes of my argument, is amply sufficient.

Diagnostic Criteria.

The question of diagnosis raises not only the previous point of what we are entitled to take as evidence of the existence of the disease, but also, and which is quite as important, what we are permitted in accepting as evidence of cure of the disease. Our own investigations on these matters have introduced us to certain perplexities. In any extensive clinical survey one not infrequently meets with a child running about and apparently quite active, and yet presenting on x-ray examination a very definite and severe degree of deficient calcification at the growing ends of the long bones. In another instance the child previously unable to walk is by some remedial measure apparently enabled to do so, but x-ray examination of the bones reveals not the slightest improvement. In still another example, also ostensibly in consequence of some therapeutic measure, the bones show very definite signs of healing, but the child remains as helpless and as disinclined to walk as ever. In the face of such findings what conclusions can be arrived at? If one is justified in ignoring the bone changes as an essential feature of cure, is one equally justified in diagnosing the disease in the absence of these same bone changes? In other words, is rickets a disease which may implicate any part of the body, but which attacks one part in one individual and another part in another? Such an assumption at the present moment, however, would tend rather to make difficulties than to help in the task of elucidation.

Diet as a Cause of Rickets.

The dietetic theory is undoubtedly of all the current theories the most popular, and to it therefore I would desire in the first instance to direct attention. As work on this aspect of the problem has proceeded, the importance of exactitude both regarding quantity and quality has become more and more apparent, and consequently much of the older clinical work must be discarded. Broad generalizations regarding diet, with no definite statements on either the exact nature or amount of food, characterize most of the work of our predecessors, and make it quite valueless as evidence in the present discussion. For the same reason I am willing to exclude our own study of the diets of rachitic

and non-rachitic families; in these studies we attempted to form some idea of the amount of the various foodstuffs consumed by the child under consideration from an analysis of the total family diet. Such a method it is readily admitted can never give more than a mere approximation of what the child really obtains. Fortunately, however, within recent years clinicians have seen the necessity for greater precision regarding these matters, and we have at our disposal for consideration several investigations with such exact information. In the infant it should be remembered the question is not really so difficult as at first sight it might appear, owing to the extreme sameness of the diet at this period of life.

The clinical dietetic investigations can be divided into three groups: prophylactic, provocative, and curative. Hess was probably the first to carry out exact clinical experiments with the idea of testing the theory that animal fat or its constituent, fat-soluble A, possessed a prophylactic power. It was well known that the negro child in New York almost invariably suffered from the disease. Hess and Unger⁴ therefore added to the diet of a certain number of those children from their earliest infancy crude cod-liver oil, and found that a much smaller proportion than usual developed the disease; in fact by this measure these authors held that they reversed the proportion of these usually attacked and those remaining free. We ourselves have also carried out a similar investigation, and found that of 27 infants receiving oil only 15 per cent. developed rickets, while of 30 controls 60 per cent. presented some evidence of the disease.

The first clinical tests to observe the behaviour of ossification in the infant while on a diet devoid of the fat-soluble A factor were also carried out by Hess.⁵ Hess removed the milk fat from the diet of a certain number of infants by feeding them on dried skim-milk, replacing the fat by cotton-seed oil so that the caloric demands were supplied in the usual representative manner. He, however, saw no evidence that these children were abnormally prone to the disease. The vitaminists of course have objected to the use of Hess's clinical experiments as bearing on the question of the rôle of fat on the ground that cotton-seed oil is one of the best of the substances poor in fat-soluble A. In 1919 we find cotton-seed oil classified by the Vitamine Committee⁶ of the Medical Research Council among those fats not protecting against rickets, yet Mellanby⁷ in his recent Oliver-Sharpey lectures states that its antirachitic power is moderate. One has a difficulty in understanding Mellanby's expression of opinion, since in his detailed work on experimental rickets, also published by the Medical Research Council, he records, in all, three experiments with cotton-seed oil, two of which developed rickets, and in the other he describes the bones as practically normal, though I must say the published x-ray picture of this special case does not substantiate this opinion. In almost immediate juxtaposition there is an identical picture from an animal of similar age fed on rape-seed oil, and believed by Mellanby to demonstrate rickets. To my mind both are definitely rachitic. Is it that Mellanby has been influenced in his opinion by Hess's clinical results? If so, then for similar reasons much of his dogmatism about fats and their antirachitic powers must be abandoned.

Other clinical tests of a provocative nature are also against the fat-deficiency theory. On the Continent during the war milk was exceedingly scarce, and this was, perhaps, nowhere more evident than in Austria. To make the milk go as far as possible Pirquet of Vienna devised the plan of doubling or even trebling its nutritive value by the addition of carbohydrate, so that the child would only require half or one-third of the usual quantity, and would thus only obtain, as the case might be, half or one-third of the normal amount of fat. In consequence of the good results gained with this type of feeding Pirquet was forced to review his older ideas of nutrition, and formed the opinion that fat was practically unnecessary, the only desiderata in the dietary being the requisite number of calories, and, on the basis that human milk is the ideal food, that 10 per cent. of these be derived from protein. He cited in support of his contention the low fat and rich carbohydrate diet of Eastern and tropical natives, just as Mellanby cites the diet of the Esquimaux as evidence for the necessity of fat. How can we reconcile two such different and apparently satisfactory diets, and the absence of rickets in both instances, with the antirachitic power of animal fat?

When visiting Vienna last spring (1921) I was informed by Pirquet and his assistants that they had not seen any ill effects from such a fat-poor and carbohydrate-rich diet, and quite recently Wimberger,⁸ one of Pirquet's assistants,

has recorded the interesting history of male twins. One of these had been fed on a fat poor diet and the other on a fat-rich diet, yet in both the osseous and general development were identical and quite satisfactory. More extended experience may, however, show that their first impressions were unduly optimistic, and we thus await with interest the report of the delegates of the Lister Institute, who, during the past two years, have been carrying out an extensive comparative study on this very point.

One must not forget in this connexion that feeding children on a fat-poor diet is no novelty. This has for years been a recognized method of dealing with certain cases of malnutrition, cases in which the error seemed to be a difficulty in digesting fat. Examples of this type of malnutrition are not uncommon, and in those which I have observed among the well-to-do there has been, to the best of my knowledge, no development of rickets, nor, I might add, any arrest of growth, this having as a matter of fact usually proceeded at a supernormal rate during the treatment. These experiences have rid me of the fear of feeding children on a fat-poor diet; but in order to test this point still further we have been observing, for some time past, infants fed on fat rich and fat-poor diets over prolonged periods, special attention being paid to changes in ossification. So far as we can judge there is no greater predisposition for the one set than the other to develop rickets, but Dr. J. D. Galbraith will, I hope, have an opportunity of supplying the details of this investigation.

Then there is the recent work of Hutchison¹⁰ on rickets in India, which makes it difficult to understand how diet can be a factor of prime importance in its cause. Hutchison found in Nasik in India two social classes almost as sharply differentiated from one another, so far as diet and housing are concerned, as could be obtained under experimental conditions in a laboratory. The one class (the poor labourer and agriculturist) lived an open-air life, and the other (the wealthy Mohammedans and Hindus) inhabited houses the rooms of which were dark and airless, and in which the infant and female populations were more or less continuously confined. The infants of both classes were breast-fed for one or perhaps two years; the general diet of the poor was deficient, in fact almost devoid of fat and especially animal fat, whereas that of the rich contained this substance in moderate amount. It should be specially noted, too, in connexion with the matter of breast feeding, that it was the wealthy classes who consumed most vegetables, milk, and eggs, recognized sources of the antirachitic vitamin. Yet it was in the better classes, those consuming the richer fat diet, that Hutchison found not only early but late rickets prevalent, the poorer classes, though eating an almost fat-free diet, being comparatively immune. It is also interesting to record in this connexion that Hutchison found dental caries to be exceedingly and equally rare in both the rich and poor of Nasik and the surrounding districts of India in spite of the relatively poor fat diet.

So far as therapeutic tests are concerned we have the record of Dr. Mackay's¹¹ experiences in a London polyclinic. She treated cases of apparently active rickets by the administration of different types of fat. Unless during the summer months Dr. Mackay did not see any evidence of cure in spite of the addition of cod-liver oil and butter to the diet. Even during the summer in one case which was receiving 6 drachms of cod-liver oil daily the condition seemed to progress, so that the improvement which resulted in some of her cases may simply have been in consequence of the well-recognized tendency during the summer months to spontaneous recovery. It is also worthy of note that Cheadle and some of the others who took part in the discussion thirty-four years ago, and who were all whole-hearted believers in the deficient fat theory and in the efficacy of cod-liver oil, said that so far as the treatment of the disease was concerned they had more frequently to stop the cod-liver oil which was being given than to prescribe it. I might also be permitted to refer here to the experimental work of McCollum and others in which healing occurred during starvation of the animals.¹²

If the absence of fat-soluble A really be of importance in the etiology of rickets, why is keratomalacia so seldom seen in conjunction with it? I personally have not observed it in one single case of rickets in Glasgow. Keratomalacia for many years has been looked upon by clinicians as a condition due to the absence of fat from the diet, and experimentalists have more recently observed this relationship. Mori,¹³ who saw a large number of cases in Japan, where the diet is notoriously deficient in fat, states that it is chiefly observed during the summer

months (July to October), and that it is invariably found in association with defective fat ingestion or absorption, and in consequence he suggested the name "lipaperia." He describes almost the same miraculous cures of the condition with cod-liver oil as we ourselves are in the habit of seeing in the case of senry with orange juice. It is interesting to read how Mori tried the therapeutic value of different fats, finding cod-liver oil the best and olive oil almost without effect. As rickets is practically unknown in Japan, Mori states that there can be no question of this disease playing any part in the cause of keratomalacia. More recently Bloch¹⁴ in Denmark has described an epidemic of keratomalacia in infants through their being inadvertently fed on a diet very poor in animal fat. If one is to admit that both rickets and keratomalacia are due to the deficient ingestion of fat, then I am afraid it is only by adopting the explanation suggested by some, that the different lesions in these two conditions are consequent on the deficiency of fat being associated with different combinations of the other constituents in a badly balanced diet—one of the most fantastic theories in modern pathology.

And finally, the fact that the disease develops on a diet of undiluted milk surely renders difficult of acceptance the suggestion that rickets is a deficiency disease, at least so far as fat and also calcium are concerned, as cow's milk contains on the average as much fat and four times as much calcium as human milk, the ideal infant food. Strictly speaking a deficiency disease is one due to insufficient ingestion, and I suppose the adherents of the deficiency theory accept this definition. Could, however, the disease be explained by deficient absorption—of fat, of phosphorus, and of fat-soluble A are the questions which arise in the etiology that some believe them to be? Though it has been shown that, at least in full-blown rickets, absorption of fat is as good as in health, we know that in the early stages of the disease calcium retention (? absorption) is very deficient, and also that the amount of inorganic phosphorus in the blood is less than normal. The absence of rickets in marasmus and coeliac disease, both chronic conditions in which absorption is probably deficient, may be accounted for by the relatively slow rate of growth in these conditions. A certain rate of growth is essential for the development of rickets. But if the question be one of defective absorption then it must be defective absorption of a very special type, a type induced by a lesion permitting of a very selective action—a lesion that allows the elements necessary for growth to be absorbed, and yet at the same time deprives the economy of those requisite for regulating that same growth. It must also be a lesion that seldom if ever occurs in the well-to-do. To my mind such a hypothesis postulates a specific infection, a possibility which we must certainly entertain.

Environment as a Factor in the Cause of Rickets.

In our investigations in Glasgow, environment and general hygiene have always seemed to be factors of importance. I need not recall my own records of 1915,¹⁵ or those carried out later by Miss Ferguson,¹⁶ and the experimental work carried out in collaboration with Professor Paton. As a result of all these studies we concluded that overcrowding, poor parental care, and absence of open-air exercise were determining factors, the latter of which I personally was inclined to consider the most important.

Hutchison's recent observations in India lend considerable support to the idea that confinement is a factor of prime importance. He showed that the incidence of rickets was definitely related to the purdah system (a system only practised by wealthy Mohammedans and Hindus), which accounted not only for the fact that early rickets attacked both sexes—all infants being naturally treated alike—but also that late rickets only attacked females, who alone were affected by this system of isolation. I have already quoted Dr. Hutchison's experiments while discussing the question of diet; you will remember it was the class which consumed the largest amount of fat, and animal fat, who were affected. It has been argued against the validity of Hutchison's work that ghee, the chief vehicle of the fat in the diet of the Indian, is heated, and in consequence the fat-soluble A factor has been destroyed. If that be admitted then the investigation becomes as clear-cut an experiment on the effect of confinement as anyone could desire.

Modus Operandi of Confinement.

But if confinement is a factor of etiological importance, in what way does it exert its influence? Is it, as I presumed,

from deficient exercise and muscular movement, or is it, as some of the recent work suggests, due to the absence of the sun's rays?^{1,2} Our own thorapontic tests with apparently active rickets rather support the former theory. We treated one series of children suffering from marked rickets with massage and electricity in hospital in town, another series in a hospital in the country, and still another series while they were resident in their own homes, the children being brought thrice weekly for treatment to the out-patient department. The cases that made the most rapid recovery, at least that were soonest able to walk, and in whom the x-ray-evidences of healing occurred with average rapidity, were those who remained in their own homes and were brought to the out-patient department for treatment. This apparently anomalous result we were inclined to ascribe to the fact that while the children remained at home they got more outings in the open air, and more exercise through the rest of the members of the family taking the child out and teaching it to walk, and because the mother, according to instructions, also massaged the limbs and encouraged the child to walk.

Huntly,³ in his paper in 1889, suggested that the freedom from rickets of the poor Indian child, in spite of the fat-poor and rich fariuacous diet, was due to the abundance of sunlight in India, and that the probable cause of the prevalence of the disease in Glasgow was therefore its comparative absence. Hutchison, too, in his paper states that he has seen rapid recovery in late rickets result from no other change than putting the patient on a balcony in the open air and sunshine, the diet being prepared at home, and being the same as that which had previously been taken.

In spite of the confirmatory experimental work⁴ on the effect of sunlight there are, to my mind, certain difficulties in accepting it as the determining factor. As I have previously mentioned, we obtained better results in our cases by leaving the children in the city and carrying out massage than by sending the cases to our country branch, where undoubtedly there is a greater abundance of sunlight. Is the relative amount of sunshine enjoyed by the rich and the poor in Glasgow a sufficient explanation of its varying incidence in the two classes? If so, then the amount of sunshine absolutely necessary for normal growth must be very trifling considering the amount that is registered in a city like Glasgow during the winter months. The complete absence of rickets in Iceland, where for four months of the year the sun never shines, is also difficult of explanation on such a theory. If such were the explanation would one not also expect to find a far greater difference between the incidence of the disease in different parts of the world? On the Continent, from the system of heating, there is less pollution of the atmosphere, and, as is well known, a much greater amount of sunshine; yet, for example, in Vienna rickets is just as prevalent as it is in Glasgow, though there are double the number of hours of sunshine per annum.

That sunlight has a curative effect I am quite satisfied, but that does not necessarily mean that its absence is the cause of the disease. Sunlight, at least in moderation, exhilarates; and may it not be that its absence induces lethargy and thus leads to deficient exercise? Does sunlight exert its curative influence because a deficiency has been made good, by stimulating metabolism, or is it because of its antimicrobial powers on some infecting agent? We have the analogy of the effect of sunlight in tuberculosis, and also of the x rays and radium in tuberculosis and sarcoma. I feel that further work on these lines must be done ere we can definitely accept the conclusion that rickets arises from absence of sunlight *qua* sunlight. Sunlight usually means open air, better ventilation, and diffusion of infection. Let us rid our minds of the obsession that rickets must necessarily be a deficiency disease, due to the absence of something, whatever be the nature of that "something."

I refrain from entering into a discussion of the relationship between human and animal rickets, but I would ask, Are we certain that the disease as induced experimentally in the animal is the same as that arising spontaneously in the child? We should, I think, be very careful before concluding that because such and such follows certain measures in the case of the growing dog or rat the same changes must necessarily occur in the growing child. This same view of course has been expressed by McCollum,⁵ one of the most extensive workers in this field. The numerous and conflicting findings in the experimental field have tempted some to suggest that there may be not only different types of rickets, but also that the disease may be dependent on many causes. Such suggestions are to my mind, if not ill advised, at least

premature, and have been brought forward more with the idea of satisfying several unsubstantiated hypotheses than because there are definite facts forcing us to such a conclusion.

Conclusions.

Can we, then, in the face of these clinical facts and considerations conclude that diet is a determining factor of importance, let alone the direct cause of the disease? The undoubted prophylactic effect of cod-liver oil certainly suggests that some dietetic constituent present in the oil might be of moment, but the failure to cure the disease even by the administration of large doses of the oil is decidedly against the idea that its action is due to it supplying some ingredient essential for normal growth. At least rickets in this respect is very different in its behaviour from the known deficiency diseases, scurvy and beri-beri.

It would rather appear that somehow or other the etiology of rickets is associated with confinement. Whether this is due to want of fresh air, lack of exercise, or the absence of the sun's rays, or because confinement, overcrowding, and bad hygiene in general favour the development of some virus, it is impossible at present to say. In fact, it would appear that it is only by enlisting the aid of some virus that we can explain not only its geographical and social distribution, but at the same time the age and seasonal incidence of the disease. These are all points, too, with which we are quite well acquainted in the life history of the infections; and, if I might be permitted to conclude with a suggestion, it would be that in both the experimental and clinical fields the idea of rickets being of the nature of an infection should be more seriously entertained and investigations with this idea in view more generally undertaken.

II.—EDWARD MELLANBY, M.A., M.D. CANTAB., Honorary Physician, Royal Infirmary, Sheffield.

It is a good thing that those of us who are actively engaged in investigating the factors involved in the development and cure of rickets should leave our work periodically in order to discuss the subject from the broadest standpoint, and to hear the criticism of both clinical and laboratory colleagues. It is more specially important that this should happen at the present time, because many results of research have been published during the past year, and, both from the point of view of the investigator, of the practising medical man, and of the public health worker, it is desirable that the new facts should be appraised, and their relative value decided upon. Fortunately, the medical profession are fully alive to the importance of the problem, largely, no doubt, as the result of the investigation initiated by the Medical Research Council. The controversy that has developed from these researches has probably been useful in attracting attention to, and intensifying the general interest in rickets. Whatever disagreement there may be among investigators as to the etiology of the disease, we all recognize that the complete eradication of rickets would do away with much bone deformity, improve the physique, lower the infant mortality, and, most important of all, improve the teeth of the people of this country beyond recognition.

But while we are agreed as to the magnitude of the problem, our views as to the most important factors in the etiology of the disease are very diverse. If, indeed, we were asked to formulate plans for eradicating rickets from this country, our recommendations would be so different as to suggest chaos. Some would strongly recommend housing schemes as a panacea; some massage and electricity applied to children from birth; some more sunlight and ultra-violet rays; while there are others who think that proper feeding of children would settle the problem.

While we are still suffering from the disability of ignorance, the narrowing down of the field by recent investigations suggests

at our present discussion will be fruitful; for important ideas have been made on the hygienic side of the problem. Dr. Hansemann formulated his theory of domestication, and the dietetic hypothesis of rickets has also become more definite and concise as the result of recent research.

Much of the recent work on rickets has centred round the particular dietetic hypothesis of rickets which I have put forward,¹ and as I am anxious that my views should be correctly understood and not misinterpreted in this discussion, I wish to state these briefly.

Rickets, according to my view, is a disease accompanying growth, and is due primarily to defective feeding. What is the rickets-producing diet? It is one of unbalanced nature in that it contains too little of those foodstuffs responsible for proper calcification of bone and too much of those substances responsible for the growth of tissue, these latter substances being either neutral or antagonistic to the deposition of calcium phosphate in the growing bony matrix. Assuming that the diet contains a sufficiency of calcium and phosphorus in a form that can be absorbed from the alimentary canal, the most potent influence for procuring the calcification of bone that I have served up to the present is something of the nature of a vitamin giving a distribution and properties somewhat similar to fat-soluble A.* On the other hand, foodstuffs responsible for growth and the laying on of tissue which are indifferent or antagonistic to calcification include the cereals. Generally speaking, therefore, rickets is a disease which follows the ingestion of diets relatively poor in the antirachitic vitamin and rich in growth-promoting elements, and more particularly in cereals.

The complication which has made this hypothesis of the aetiology of rickets difficult to grasp is the new conception that the various essential factors of a diet are so interdependent that many dietetic problems must be considered from the point of view of balance, and that it is no longer possible to speak of "excess" or "deficiency" of substances in an absolute way. For instance, the amount of fat-soluble vitamin which may be sufficient in one diet becomes a relative deficiency when more cereal is eaten, or the calcium in one diet may be adequate but will become inadequate if the fat (butter) be greatly increased. In general, the minimum of any substance essential for perfect health and development is a variable dependent on the other factors of the diet eaten. The new dietetics which insists on the importance of quality as well as quantity must also find a way of expressing the fact that the value of a diet depends on the relative amounts of its essential constituents and not on absolute amounts.

It seems necessary to mention this point of view of diet, for much of the criticism against my work has been written as if I had suggested a kind of penny-in-the-slot hypothesis of rickets: abundant fat-soluble A in the diet, no rickets; absence of this vitamin, rickets. It ought to be superfluous for me to say that I have never written of rickets as a disease of this simple aetiology. I wish also to take this opportunity of saying, in view of statements made in various places that I have altered my views, that I have not written of rickets as a disease uninfluenced by exercise and general environmental conditions. I have, however, always insisted that diet was the most predominant factor, and that environment was of secondary importance. Good hygienic conditions, in so far as they lead to greater activity and greater exposure of the skin to the ultra-violet rays of the sun, will no doubt prevent a moderate diet from producing the disease. Bad hygienic conditions will have the opposite effect, but, in my experience, a good diet will prevent rickets however bad the environment may be, and a really bad diet will result in rickets under the most perfect surroundings.

I propose now to deal with some of the more salient features of recent work in the light of my experimental results on animals, and, during the past eighteen months, of clinical observations on rachitic children.

THE INFLUENCE OF DIETETIC FACTORS ON THE DEVELOPMENT OF RICKETS.

(a) *The Interaction of Fat-soluble Vitamin, Calcium, and Phosphorus.*

In my experiments on dogs no difficulty was experienced in producing rickets by diets which contained abundant calcium and phosphorus, but were relatively deficient in fat-soluble A,

I shall call it the fat-soluble or antirachitic vitamin throughout this paper.

so long as sufficient food was eaten. On the other hand, Korenechevsky² has found that, whereas the absence of fat-soluble vitamin in the diet only produces true rickets in a certain number of young rats, where there is an additional deficiency of calcium rickets develops in 100 per cent. of cases. Similarly McCollum and his associates,³ also working on rats, found that a deficiency in the diet of an element present in large quantities in cod-liver oil (I shall assume for brevity's sake it is the fat-soluble vitamin) only produces osteoporosis, but, combined with a deficiency of phosphorus or calcium, and especially the former, in the diet, allows definite rickets to develop. The point of agreement in these various researches is that the fat-soluble vitamin in the diet has a potent effect in promoting calcification of bones, and what remains to be decided is the relative importance of calcium or phosphorus deficiency in the aetiology of rickets.

The necessity of having a sufficiency of calcium and phosphorus in the diet before an abundance of good bone can be formed is obvious. If either is deficient during the growth of an animal, a condition of osteoporosis must result, but, whether it will be simple or complicated with rickets, will depend on the rest of the diet. Before discussing the matter further it may be well to state that I have already supplied evidence in support of the suggestion that the balance of calcium, phosphorus, and fat-soluble vitamin in the diet is important in ways more obscure and subtle than the simple deficiency of one or more.

I have shown, for instance, that too much butter in a given diet may result in bones defectively calcified, and that the antirachitic effect of butter is best obtained when it is balanced with a sufficiency of calcium. Again, the different action of caseinogen as present in milk, and that of acid-caseinogen as prepared from milk by acid precipitation—a substance deprived of its calcium—seemed to be most easily explained by some alteration in the calcium-phosphorus ratio. I mention these facts in order to show that I have previously considered the question of calcium and phosphorus in relation to the antirachitic vitamin, and suggested that it might be of importance in some special cases. I doubt, however, whether it has the practical importance in human rickets that the recent results obtained by different investigators, working on problems of rickets in rats, have suggested.

One possible cause of the difference in the experimental results of different workers may depend on the type of animal used—for whereas later investigators have worked on rats, my experiments were made on dogs. The differences in reaction to dietetic changes found among various animals are so notorious now that this point requires no emphasis. For instance, the failure of rats to develop scurvy in spite of the absence of the antiscorbutic vitamin from the diet is well recognized. Consequently, if there should happen to be any difference in reaction to diet between rats and dogs, which cannot be explained by differences in technique, then, in so far as the results have to be extended to children, I should unreservedly support the dog experiments, because of the closer similarity between the metabolism of a human being and a dog than between a human being and a rat.

There are, however, technical variations in the experimental methods adopted, which may explain the apparent discrepancies in the results. For instance, the dietetic conditions under which the rat-feeding experiments have been carried out were more strenuous than mine, more particularly in respect to the fat-soluble vitamin eaten. In the rat experiments a point has been made to eliminate this substance from the diet, whereas in my experiments on puppies the amount of separated milk allowed was fairly high, and must have contained some of this vitamin. Since cutting out the fat-soluble vitamin from the diet of rats stops growth after a short time, and since, in my opinion, rickets is a disease of or accompanying growth, it would not be expected that the preliminary slow growth, and the ultimate marasmus associated with this defect in diet, would be accompanied by a great development of rickets. It seems to me that, if the rats' diets contained a relative rather than an absolute deficiency of fat-soluble A, the better growth that would result therefrom might be compatible with more euphatic rachitic changes of bones, and these might possibly develop as in the puppy experiments even when the calcium and phosphorus contents of the diet were not deficient in amount. Not only do the conditions of feeding in the rat experiments call forth

this criticism, but, as human rickets is the problem to be solved, the diets used are abnormal in ways not commonly met with in the feeding of children. It is unlikely that human diets, except under rare conditions, should be so deprived of fat-soluble vitamin as are the synthetic diets of Sherman and Pappenheimer,⁴ and Korenchevsky,² in their rickets experiments on rats. If this did happen, much more keratomalacia would be found among children. It has been argued by some that the fat-soluble vitamin cannot be an important element in rickets because, under experimental dietetic conditions which result in keratomalacia owing to the absence of this vitamin from the diet, rickets does not necessarily develop. This criticism seems to me to miss the point of my work, for, whereas keratomalacia appears to result from a simple defect of diet—namely, the absence of the fat-soluble vitamin—rickets is more complicated in that, so far as the bone is concerned, it is the outcome of a race between growth of bone and calcification of that bone. The antirachitic vitamin reacts with calcium and phosphorus on the diet, and thereby controls the actual calcification process, but there are other factors involved in the development of rickets, such as the amount of cereal eaten, and these additional factors make the two diseases of malnutrition under discussion largely independent, although one and the same dietetic factor plays an important part in the etiology of each disease. Keratomalacia is a rare disease because it is only seldom that the diet is practically devoid of fat-soluble vitamin, but, on the other hand, a relative deficiency of this substance in many articles used in the feeding of children is common, and rickets is widespread.

Further, it is unlikely from a consideration of diets which produce rickets in children that the calcium and phosphorus deficiencies are of prime importance. This remark applies more particularly to the question of phosphorus, the importance of which is being stressed in many recent publications. Although children develop rickets when the calcium content of the diet is adequate, it is true, nevertheless, as I have pointed out elsewhere, that a diet deficient in fat-soluble A is likely to be deficient also in calcium, for these substances are often closely associated in their distribution in natural foodstuffs. For instance, milk, egg yolk, and green vegetables are rich sources of each, whereas flour, rice and maize, pulses, potatoes, sugar, and jam are almost devoid of both. When, however, we consider the phosphorus content of various foodstuffs and their relation to rickets, there is no evidence that phosphorus deficiency is a problem of practical importance, although the observations of Sherman and Pappenheimer⁴ and Shipley, Park, McCollum, and Simmonds⁵ on this point may be of great scientific interest. It has been said that a combined deficiency of phosphorus and fat-soluble vitamin in the diet produces more typical rickets than that produced by a deficiency of calcium and fat-soluble A. I am unable to pronounce any opinion on this point, but I have little doubt that some specific relation exists between the antirachitic vitamin and phosphorus. In 1918 I failed to obtain any evidence that this vitamin had the direct influence on the formation of calcium carbonate in eggshells that it exerts on the combination of calcium and phosphate in bone. Parenthetically, I wish to allude here to the experiments of Pappenheimer, McCann, and Zucker,⁶ made to test the efficacy of the fat-soluble vitamin in preventing rickets and in promoting the deposition of calcium phosphate in bone. They failed to show that the vitamin exerted such influence, but as they first took the precaution to remove most of the phosphorus from the diet their experiments will probably not be accepted as crucial.
